tearing and heavily damaging the surrounding organs, its kinetic energy is consumed almost on the spot and it either does not move forward at all or only a little.

(5) In the case of a shot fired at close quarters, the force of the impact depends not so much on the distance travelled by the bullet within the body as on the violence of the explosion.

(6) Elastic tissue, when relaxed, *resists a projectile*, gradually giving way like a spring; but, when *stretched, will not stop the projectile.*

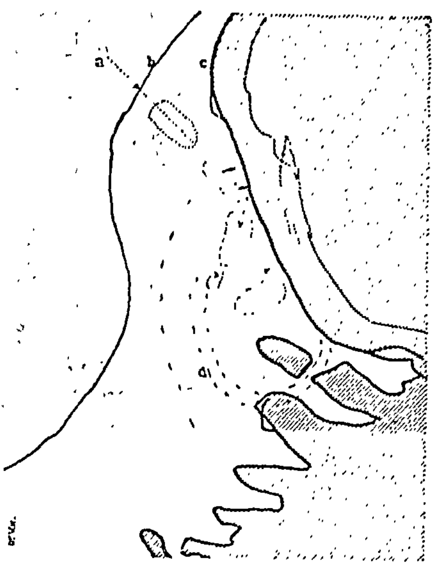

Fig. 3—Key to fig. 1 : *a*, presumed course of bullet ; *b*, external surface of soft parts of nape ; *c*, external occipital protuberance ; *d*, wall of cavity excavated by bullet.

Most probably the bullet struck the occipital bone at *an acute angle—i.e., grazed it—and the septum nuchae* was relaxed when the shot was fired, for we may assume that the victim had lifted her chin and bent her head somewhat back purposely to try to see from under the bandage over her eyes while being led to the ditch, and as a reflex action when her neck, bandage, or hair was touched with the barrel of the pistol.

The fact that a shot which is commonly lethal proved ineffective in the present case supports Kenyeres's statement that "one should be very careful as to the expression of an opinion about danger and recovery in gunshot injuries." It also confirms Kogel's view of the value of evidence : "no photograph, no evidence, no decision." Radiograms should be taken of every gunshot injury ; in fatal cases they should be taken before necropsy. The projectile may sometimes be found facing an unexpected direction and surprisingly far from or, as in the present case, near the wound. *In addition to showing the nature of the fracture, if present,* and the anatomical position of the projectile, radiography enables conclusions to be drawn about the type of weapon used and the direction and distance at which it was fired.

SUMMARY

An unsuccessful attempt at execution is described. A pistol-shot fired at close quarters into the back of the neck did *not kill the victim, who made a complete* recovery.

Presumably the bullet glanced off the occipital bone and spun round, damaging the soft tissues alone.

The *importance of radiography even in fatal cases of* gunshot wounds is emphasised.

Preliminary Communication

BACTERIOPHAGE AS A FACTOR IN EPIDEMIOLOGY AND BACTERIAL EVOLUTION

LYSIS OF DIPHTHERIA BACILLI BY STAPHYLOCOCCAL BACTERIOPHAGE

Like those of other bacteria, strains of the diphtheria bacillus *differ widely in virulence, growth characteristics,* and fermentation reactions, and more than 60 different serological types have been described.[1] The ordinary processes of bacterial variation and natural selection do not adequately account for this diversity of strains. For, although mutation is known to occur in bacteria as in other living organisms, the presence of one mutant bacterium in a population of say *100 million*, would not be expected to affect the behaviour of the culture as a whole. *Of course, if the mutant had superior survival-powers* and multiplied more rapidly it might in time overgrow other organis[illegible] become predominant. But if this [illegible] strains would inevitably become more and more coarse-growing, whilst slow-growing and fastidious pathogenic organisms would disappear. The frequent occurrence of strains *of pathogenic organisms of widely different properties,* and the absence of any apparent evolution towards coarser and less fastidious growth requirements, suggests the presence in Nature of selective agents favouring the multiplication of mutants regardless of the general vigour of their growth.

EXPERIMENTAL EVIDENCE

I have lately been able to show[2] that, in relation to the diphtheria bacillus, bacteriophage is just such an agent. Diphtheria bacteriophages are type-specific and when added to a culture they lyse the great majority of the organisms, leaving intact only mutant bacteria which differ from the other cells in the culture in being resistant to the *bacterial virus.* Not *only do the* organisms which grow out from a lysed culture differ from the parent strain in being resistant to the lethal and lytic action of the bacteriophage, but they often differ in other characters as well.

As an example, the case of *mitis* type III diphtheria bacilli may be considered. A phage was isolated which *lysed a strain of this type,* but when it was tested against other strains of the same type only some of these were found to be susceptible to its action and the others were completely re[illegible]. Although identical serologically, as tested by [illegible] the *mitis* type III strains were thus divisible into two subtypes, *according* to their phage-susceptibility. Furthermore, the phage-*resistant strains* were all virulent and toxigenic, *whereas* the susceptible strains were avirulent and *produced* no diphtheria toxin. When the susceptible strains were subjected to the action of the bacteriophage, organisms grew out which were resistant to lysis ; and a number of these phage-resistant mutant strains were found to be fully virulent and toxigenic. Thus phage had been shown to be an agent capable of *completely transforming* the biological characters of a bacterial *strain* in a single subculture.

That this transformation is not an isolated phenomenon is confirmed by the recent work of Freeman,[3] Parsons and Frobisher[4] and Freeman and Morse,[5] who describe a bacteriophage which in contact with an avirulent strain of *diphtheria bacilli produced* virulent organisms. The presence of carriers of avirulent diphtheria bacilli among fully immunised children, as recently reported by Bradshaw et al.[6] cannot be dismissed as of no significance, since, in the presence of bacteriophage, avirulent strains can become virulent and *might* start an epidemic among unimmunised contacts now that the proportion of immunised *children is declining.*

Thus it has been demonstrated that bacteriophage is an agent capable of selecting mutant strains and completely altering the characteristics of pathogenic organisms; but it remains to be shown that this happens often enough to be of epidemiological importance. When eight diphtheria strains, selected at random, were investigated it was found that five of them were carrying bacteriophage and this property persisted on subculture. The bacteriophages did not lyse the strains which were carrying them but could readily be adapted to lyse a wide variety of strains of other serological types. It appears, therefore, that a considerable proportion of diphtheria strains occurring in infections carry bacteriophage. Should a patient be infected with both a phage-carrying strain and a strain susceptible to the phage, modification of the susceptible strain would occur. The susceptible organisms would be lysed, and only phage-resistant mutants would survive; so contacts of the patient would be exposed to infection with mutant strains differing from the parent strain.

[4] Parsons, E. I., Frobisher, M. *Proc. Soc. exp. Biol. Med.* 1951, 78, 746.
[5] Freeman, V. J., Morse, I. U. *J. Bact.* 1952, 63, 407.
[6] Bradshaw, D. B., Dixon, C. W., Mawson, F. M., Turner, G. H., Zinnemann, K. S. *Lancet*, 1952, i, 558.

A mechanism exists, therefore, by which infections can change their character; but, for this mechanism to operate, the patient must be infected by more than one strain of the diphtheria bacillus. Such multiple infection has been observed from time to time and is probably commoner than is generally supposed. Usually the pathologist has to be content when he has isolated a single strain of the diphtheria bacillus from a patient, and he cannot undertake, in each case, an exhaustive investigation of a statistically significant number of bacterial colonies.

However, even if it is accepted that infection with more than one strain of *Corynebacterium diphtheriæ* does occur in a number of patients, it must be conceded that the coincident occurrence of a phage-carrying and a phage-susceptible strain in the same patient must be comparatively rare. If bacteriophage is to be incriminated as the principal agent controlling the frequent variation in strains which is encountered in infections, a more likely conjunction of circumstances must be sought.

The question arises whether the only kind of phage that can alter the character of a micro-organism is one carried by another organism of the same species. Perhaps a strain can be altered by phage from some quite different organism which the patient happens to be harbouring?

Staphylococci are present in so large a proportion of nose and throat swabs that we can be sure that almost all diphtheria strains have been in contact with staphylococci at some stage in their history. Moreover, I have noticed that diphtheria strains isolated from swabs heavily contaminated with staphylococci often show modified properties. Accordingly, I have investigated the possibility that staphylococcus bacteriophage can affect diphtheria strains.

When *Staphylococcus aureus* bacteriophage no. 47 (which had been propagated on *Staph. aureus* strain 36) was tested against various diphtheria strains, there was no visible effect. However, after a few subcultures of the bacteriophage with diphtheria strains, filtrates were obtained which lysed the diphtheria strains. Thus staphylococcus phage had been converted to diphtheria phage. To confirm this finding, three more staphylococcus phages were examined (phages 58, *muscæ*, and 3A, which had been propagated on *Staph. aureus* strains OxH, *muscæ*, and 284 respectively) and each of them yielded phages which lysed diphtheria strains after a few subcultures with the appropriate diphtheria strain. Like diphtheria phages obtained from phage-carrying diphtheria strains, those obtained from staphylococcal phages were type-specific but could readily be adapted to lyse a variety of other types of *C. diphtheriæ*.

COMMENT

The observation that staphylococcus bacteriophages can readily be adapted to lyse diphtheria bacilli provides a reasonable explanation of the wide variety of diphtheria strains encountered in infections, since the presence of staphylococci in the nose and throat of diphtheria patients is very common. I do not, of course, suggest that this relation between bacteriophage and bacteria of different species is confined to *Staph. aureus* and *C. diphtheriæ*. On the contrary, through the intervention of bacteriophages from phage-carrying strains, coincident infection with different bacteria may modify the character of many other pathogenic organisms. Indeed, the apparently inexplicable rise and fall in the severity of epidemics may be explained, at least in part, by the selective action of bacteriophage. One would expect that in the intestinal tract the complex interplay of phage-carrying organisms and susceptible strains would result in modification of the flora by the selection of resistant mutants; and this may account for the wide variations seen, for example, in the salmonella group.

The origin of "specific" bacteriophages, apparently active only against one type of organism, is more intelligible when one recognises that phages active against one species of bacterium can be adapted to lyse not only different serological types but also different species of bacteria.

There has been a tendency to regard bacteriophage as of mere academic interest, or at most as a useful laboratory tool for the typing of strains. But it now seems probable that phages are important agents in the modification of infections and epidemics and in the evolution of bacteria.

I am indebted to Dr. R. E. O. Williams for samples of staphylococcus phages and the *Staphylococcus aureus* strains on which they are propagated.

INSTRUMENT FOR RETROGRADE NAILING

ONE of the few disadvantages of the retrograde method of inserting intramedullary nails has been the technical complication necessary to avoid blunting the ends of the nail. The instrument illustrated, used in conjunction with a standard nail slotted and sharpened at both ends, provides a simple means of driving a nail in either direction without damage to the cutting surfaces, by enabling the driving force to be applied directly to the slot.

The original model was made for me by Mr. Robert Fraser, chief orthopædic technician, Stracathro Hospital, Brechin, and the model illustrated has now been made by Messrs. Down Bros. & Mayer & Phelps, whose help I gratefully acknowledge.

Reviews of Books

Causes and Prevention of Tuberculosis

BRICE R. CLARKE, M.D., consultant physician, Northern Ireland Tuberculosis Authority; lecturer in tuberculosis, Queen's University of Belfast. Edinburgh: E. & S. Livingstone. 1952. Pp. 288. 32*s*. 6*d*.

THIS book comes at an opportune moment to correct the present tendency to separate the preventive and curative sides of the tuberculosis services. Surprisingly, Dr. Clarke does not mention this unfortunate effect of the National Health Service Act, probably because a special authority to deal with all aspects of tuberculosis work has been established in Northern Ireland.

The first two-thirds of the book set out what is known of the pathogenesis of tuberculosis. The references are unusually full for a textbook. The various causative relationships are described, but it is doubtful whether the balance between them is fairly held. The genetic factor receives less than its due, since Dr. Clarke avowedly believes in the major part played by infection, even in family contacts. The last chapters deal with the prevention of infection, and methods of immunisation and of preventing disease in the infected individual are also discussed. Dr. J. Ritchie contributes a chapter on mass miniature radiography.

The presentation is clear throughout, but it is a pity that in quoting from Scandinavian sources Dr. Clarke has copied the meaningless term "inversion" of the tuberculin reaction where most English doctors would use "conversion."

Rheumatic Diseases

Based on the proceedings of the Seventh International Congress on Rheumatic Diseases. Editor: CHARLES H. SLOCUMB. Philadelphia and London: W. B. Saunders. 1952. Pp. 449. 60*s*.

THERE is a place in any subject for something between a formal textbook and current literature. This is such a book, and is the result of wise exploitation of the proceedings of the seventh International Congress on Rheumatic Diseases. Over ninety papers are presented here, a few in abstract but most in full; and to some of the more important papers reports of the discussions are attached. Some—such as the early reports on the use of cortisone and A.C.T.H. in the treatment of rheumatoid arthritis—are by now distinctly dated; but papers on other, slower-moving topics—such as the relation of the group-A hæmolytic streptococcus to acute rheumatic fever—are well up to date. The twenty chapters range through general information about the rheumatic diseases to rheumatic fever, rheumatoid arthritis and its variants, fibrositis and psychogenic rheumatism, osteo-arthritis, various approaches to treatment of rheumatoid arthritis, uncommon rheumatic syndromes, and reports of experimental work in all fields. Careful editing and indexing, and good printing, unify the diversity of these contributions and make most of them interesting reading.

The Alkaloids

Chemistry and Physiology. Vol. 2. Editors: R. H. F. MANSKE and H. L. HOLMES. New York: Academic Press Inc. 1952. Pp. 587. $14.50.

THE first of the projected four volumes of this treatise appeared in 1950 and was reviewed in these columns.[1] This second volume contains nine monographs, each written by an expert and dealing with a group of chemically or biologically related alkaloids, such as the indole group and the alkaloids of Erythrina spp., which are of special interest because of the diligence with which they have been examined, and the curare-like activity of the alkaloids. Most of the monographs are followed by comprehensive tables giving, with references, the principal physical constants of the alkaloids discussed, and of their derivatives and degradation products. The book is thus well documented and should prove a useful and convenient source of information.

The monographs on the Strychnos alkaloids and the morphine group, contributed by H. L. Holmes, are, in two parts, the first in each case being the original monograph, and the second (written partly with G. Stork for the morphin group) an addendum recording recent developments. Inconveniently for readers part I of the section on the Strychno alkaloids comes at the end of vol. 1, while part II is at th end of vol. 2. The chemistry of these two groups is comple and difficult, and Holmes has been remarkably successful i presenting a clear and interesting account, generously illustrated by graphic formulæ, of the vast amount of practica and theoretical work on their structure.

The other monographs are rather more conventional i treatment and are also well done. J. W. Cook and J. D Loudon tell the full story of colchicine, with its occurrence estimation, extraction, and characteristic reactions, givin a lucid and readable statement of its structural chemistry and ending with a comprehensive discussion of its biologica effects, including its mitotic poisoning effect, the attempt to apply it to the treatment of tumours, and its use in th production of polyploidy in plants.

Freezing and Drying

Report of a symposium held in June, 1951. Editor: R. J. C. HARRIS. London: Institute of Biology. 1952. Pp. 206 15*s*.

IN this book there is something for everyone interested in drying by sublimation, from high-powered technicalitie to the problems of drying an infusion of tea (which, incidentally, loses its characteristic bouquet in the process). The drying of antibiotics and foodstuffs form an introduction to the greater difficulties in achieving functional survival after the freezing and partial dehydration of skin grafts, tumour cells, blood corpuscles, spermatozoa, and "vinegar eels." The evidence is conflicting on the effect of extremely rapid freezing—vitrification—in preventing the formation of ice-crystals, and of the speed of thawing the frozen material, but it is agreed that glycerol or glucose exert some protective action essential for functional—as distinct from structural—survival of tissue cells.

Viability in dried bacteria and viruses depends more on the suspending fluid than on the method of the drying process; some technically inefficient methods seem to give as good survival-rates as those which are theoretically more efficient. Vacuum-freeze dehydration can be used by histologists to replace the older fixation methods, and seems to be particularly useful in combination with fluorescent microscopy; it can be applied to thin slices of tissue embedded in collodion to make preparations for electron microscopy. In cytochemical work the freeze-dried tissue has advantages over the chemically fixed in that the cell constituents are retained unaltered both in site and in composition.

The report includes good reproductions of photographs of apparatus and many fine micrographs of tissues.

Survey of Compounds which have been tested for Carcinogenic Activity

(2nd ed.) JONATHAN L. HARTWELL, National Cancer Institute, National Institutes of Health, Bethesda, Md. Public Health Service publication no. 149. Washington, D.C. 1951. Pp. 583. $4.25.

THIS survey covers publications dealing with chemical compounds tested for carcinogenic activity from 1880 to the end of 1947. In all, 1329 compounds are listed, of which 322 were reported to cause malignant tumours and 35 benign. The corresponding figures for the previous edition up to the end of 1939 were 696, 169, and 23. No mixtures such as tar or articles of diet are included. Data are tabulated with references to authors in chronological and alphabetical order, of animals used, strain, type and sex, preparation, dose solvent, site and route, animals with tumours, survival-time, and duration of experiment. The type of tumour is given in a footnote. Apart from these items the scope of the publications referred to is not indicated. Thus each must be consulted for other purposes. Warning is given not to carry over, without reservation, to man conclusions based on animal experiment. In the monkey none of the powerful carcinogens has been shown to produce tumours. A bibliography, indices of compounds tested, route and site of application, tumour site, species including man, and vehicle in which application was made, complete a very valuable volume.

THE LANCET

LONDON: SATURDAY, AUGUST 9, 1952

Nurses in the Making

GIRLS in their 'teens are often afflicted with an urge to do good; and if some irresponsible power compelled them to carry out their secret projects we might be flooded to the point of inconvenience with saints, nuns, missionaries, and self-immolating heroines by land, sea, and air. Fortunately many of them change their minds and take to less exacting courses.

Nursing can appeal both to the romantic imagination of the 15-year-old and the practical desire to do a useful job natural to the girl reaching maturity. Headmistresses often deplore that girls who leave school at 15 or 16 burning to nurse are lost to the profession because no-one fosters the flame until they are old enough to begin training; and in an attempt to keep that interest alive many cadet schemes have been started in our hospitals. Now that the minimum age for entry to training has been fixed at 18[1] protests about the gap between school and hospital are likely to multiply; and it may be necessary to remind ourselves that in some, at any rate, of these young people the fire will burn itself out as the endocrine upheaval subsides. Time is a good test of earnestness; and if the later age of entry loses us some recruits who looked promising as school-leavers, it may also deter in good time many who might contribute to a high wastage in the first few months of training. At the moment recruitment is higher than it has ever been: the report just issued by the King's Fund[2] mentions that the numbers of student nurses in our hospitals have risen from 46,655 in 1947 to 58,270 in 1951, and there has been a small further rise since then. For the first time in many years, in fact, we are in a position to consider the quality, as well as the quantity, of the new entry.

Nevertheless the higher age of admission is bound to affect recruitment, even if only for a time, in those hospitals which have been accustomed to take girls aged 17½ or less. From an inquiry made by the *Times*[3] it appears that some hospitals—among them a few provincial teaching hospitals and some provincial and Metropolitan non-teaching hospitals with nurse training schools, as well as many children's hospitals—think they will be seriously hampered. They may be taking too dark a view, for in cases of real hardship the General Nursing Council has power to relax the rule until the situation adjusts itself; and in any case those girls under 18 who have already started training are to be allowed to continue. Difficulty should not be acute after the coming six months, at the end of which the current 17½-year-olds will have matured to the right age. A few may be lost to other occupations in the interval, but it is hard to believe that the keener ones will be defeated by the setback. For those who are not, an added six months of growth, particularly if it is coupled with further education, can hardly fail to be an advantage. It means that, on the average, the girl's resistance to childish ailments will be greater, her bones and muscles stronger for lifting, and her endocrine balance—and hence her emotional fortitude—six months nearer maturity. We can hardly, in these days, urge Miss NIGHTINGALE's view that a nurse entering training should be 25, but we can at least give hearty support to the ruling that she should not be less than 18, even if it means some staffing difficulties at the outset.

It may not be generally understood, however, that, for the purposes of this regulation, "training" means training for the general State register or one of the supplementary registers (of nurses holding a certificate in sick children's nursing, infectious-diseases nursing, mental nursing, or the nursing of mental defectives). Orthopædic and eye hospitals, and (very unfortunately) tuberculosis sanatoria, thus fall outside the regulation: as they do not train nurses for any State certificate they are at liberty to take them below the age of 18. This matters less, perhaps, in orthopædic and eye hospitals than in sanatoria, which often have difficulty in getting enough staff. The position has been eased in many of the larger sanatoria by the secondment of nursing staff from general hospitals—a practice which, as the King's Fund points out, is largely responsible for the reopening of 3723 more beds by sanatoria during 1950–51. But some of the smaller sanatoria have been known in the past to accept 16-year-olds, and even 15-year-olds, some of whom, as Dr. ESTHER CARLING[4] notes, acquired tuberculosis. In addition there are many non-training hospitals and nursing-homes which can still employ girls under 18.

For the prospective nurse, the extra six months' delay is likely to create financial problems. The G.N.C., the Ministry of Health, and the Ministry of Labour urge girls to stay on at school, if possible, until they are old enough to enter hospital—or at any rate until they are 17. Some, of course, cannot afford to do this; and the question then arises how can they best fill the gap? Should they take a pre-nursing course, join a hospital cadet scheme, enter a hospital as a "juvenile worker," or go into some stopgap job? This question is not easy to answer in a word. Where the local authority offers a pre-nursing course the girl who has left school at 16 or 17 probably cannot do better than take it. She will be given further education as well as instruction in the subjects for the preliminary State examination, and she can usually get a grant from the local authority to carry her through. A good second choice is a job in a nursery school, if there is one to be had. Girls who leave school at 15 may not be old enough even to be accepted for a pre-nursing course. Many hospitals seek to attract these into cadet schemes, some of which are good, some not so good. The young people wear a simple uniform, have some class work, and spend the rest of their time acting as messengers and helpers in the various departments of the hospital other than the wards; and they are paid a small wage. A good cadet course, such as that described by Mr. S. HODKINSON,[5] keeps up their interest in nursing, and prepares them to enter the wards with a sound idea of what a hospital does and how it does it. But not all schemes are so well organised: sometimes the young girls are used far too freely as extra pairs of hands, and even find themselves in the wards helping in nursing duties, such as the serving of meals. Moreover the wage, though small, can be a dangerous attraction; girls have been known to leave pre-nursing courses, and even to leave school early, to go and work as juveniles in hospitals. They can hardly be blamed: the combination of drama with remuneration would be almost irresistible to almost any young person. Nor do these schemes of juvenile employment always fulfil their intended purpose; both the matron of Addenbrooke's Hospital [6] and a sister tutor [7] have pointed out the weaknesses. The girl who has been pottering about a hospital for three years before she starts her training has sometimes lost much of her initial zest, and may give up the whole idea from boredom. Moreover if she completes her training she has led an unusually regimented life from childhood on: she has not had much chance to grow into a fully mature person. There are good arguments for the view that whatever a girl does between leaving school and starting her nursing training, at least she should keep clear of hospitals: let her work in a nursery school, a shop, an office, a hairdresser's, or a circus—anywhere where she will meet people as they live, anywhere but in the laundered setting of her future profession. Nursing training, like a training in medicine, can be dangerously narrowing. It is true that, unless caught young, some girls will inevitably find their way into other careers; but while recruitment is at its present pitch we can face that: the keener ones will keep to their purpose, and the others might in any case have fallen out. A more important objection is that the alternatives open to the school-leaver of 15 may not be such as to help her to mature; they may even be actively damaging. Certainly it may be doubted whether work in a chain store, or as a cinema usherette, is likely to fit her for nursing better than a well-planned cadet course. Clearly the best way of filling the gap varies in different localities and for different people. Fortunately the King's Fund Nursing Recruitment Centre is able to give informed advice, and is now commonly approached for guidance by headmistresses who have candidates for nursing among their leavers.

Pharmacology of Isoniazid

BECAUSE such promising, and at times startling, results have been obtained with isonicotinic acid hydrazide (isoniazid) in the treatment of tuberculosis, and because, to quote the statement of the American Trudeau Society,[8] "preliminary observations in man indicate that there is little significant or serious toxicity," comparatively little consideration has yet been given to the pharmacological behaviour of this drug or its derivatives. But more information on this subject is certainly required; for unexplained side-effects often appear during treatment, and the many new derivatives that are being prepared in the world's laboratories will soon lead, despite some official control, to the extensive use of these compounds in clinical medicine.

Chemically, isoniazid is a pure synthetic substance of relatively simple molecular structure, obtained in almost colourless crystals and readily soluble in water. Laboratory assay may be performed by an iodometric method,[9] but estimation in body-fluids is more difficult. Photometric, colorimetric,[10-12] and biological[13] techniques have been devised, but to what extent they are specific or even accurate remains to be seen. For the moment, then, the available data about the distribution and fate of the drug in the body must be accepted with reserve. After giving isoniazid by mouth to mice and dogs, RUBIN and his associates [14] found that it was rapidly absorbed. ELMENDOFF et al.[15] confirmed this observation in man, and showed that after a single oral dose of 3 mg. per kg. body-weight, plasma concentrations of 1·3–3·0 µg. per ml. were reached between one and six hours later, the level remaining at or above 0·40 µg. per ml. for from six to twenty-four hours in all. A similar picture is given by RUBIN and his team [12]; their curves of plasma level against time suggest that a peak is reached in a matter of a half to two hours, that the level falls quickly in the next six to eight hours, and that no significant amount is detectable after twenty-four hours. There is, moreover, no evidence of accumulation after repeated doses. In patients with meningitis appreciable quantities of the drug were present in the cerebrospinal fluid within three hours of an oral dose of 2–3 mg. per kg., and the plasma levels were in fact much higher than those known to inhibit sensitive strains of the tubercle bacillus in vitro. Incidentally, the administration of 5 ml. of a 2% solution of isoniazid—i.e., 100 mg.—has been safely accomplished by the intrathecal route. A large proportion—from 50 to 70%—of an oral dose has been shown to appear in the urine within twenty-four hours; and a small amount is also voided in the fæces. Whether isoniazid remains extracellular or penetrates the cell membranes is not yet established; but it is significant that SUTER [16] has shown by the Mackaness technique that the minimal concentration of the new drug which causes complete inhibition of the tubercle bacillus within the phagocyte is identical with that which has a similar effect on organisms suspended freely in 'Tween-albumin' medium. The inference is that isoniazid (unlike streptomycin) readily finds its way into the phagocytes, and, by the same token, may enter other cells as well.

BENSON and his colleagues [17] remark on the paucity of pharmacodynamic effects with the isoniazid compounds. Therapeutic doses given to animals did littl to alter intestinal activity; they did not suppres salivation or lacrimation; they had no antipyreti action (a relevant point because the fever of tuber culous patients very often subsides after givin

isoniazid); and they produced no significant change in the blood-pressure. Only high concentrations of isoniazid inhibited the activity of isolated intestine—again an interesting observation, for constipation may occur in treated patients. With the exception of a definite bronchiolytic action by the isopropyl derivative on cholinergically induced bronchial spasm in the guineapig, there was little evidence of parasympathetic activity. Investigating acute toxicity, RUBIN et al.[14] showed that for mice and dogs the therapeutic ratio was generously wide. The animals succumbed, after excitement and convulsions, to death by respiratory failure. It seems more than likely that this was the result of a direct stimulation of the central nervous system, especially now that P'AN et al.[18] have demonstrated that barbiturates give protection against these toxic effects. The changes which may follow long-continued treatment are possibly of greater importance. Animals so treated lose appetite and weight, become ataxic, and have convulsions; jaundice, with fatty degeneration of the liver and kidneys, has also developed. But these alarming results have followed doses higher than those generally given therapeutically, though the margin is not great. More encouragingly, they are reversible in most cases as soon as the drug is withdrawn. In man the side-effects recorded include constipation, difficulty in starting micturition, twitching of the extremities, exaggerated reflexes, headache, vertigo, drowsiness, dryness of the mouth, eosinophilia, and slight anæmia. These have seldom been of serious consequence, but, as there now seems to be a tendency to give larger doses of the drug, and as further derivatives are coming into use, an even closer watch must be kept for these danger-signals. When they are observed, details should be sent to the Committee on Therapy of the American Trudeau Society, as requested by Dr. D. T. Carr in a letter in our last issue.

Bacteriophage and Epidemiology

MANY years ago, when TWORT described a transmissible agent which attacked staphylococci,[19] and D'HÉRELLE extended the study of *Bacteriophagum intestinale*, the hope arose that a virus of this kind might be used against bacterial infections. In treating patients, it was thought, bacteriophage might eliminate the invading bacteria, and in preventive medicine it might, for example, get rid of the cholera vibrios in a contaminated well. But these hopes were frustrated. In the first place bacteriophages were found to be highly specific and to attack only closely related strains; which meant that an extremely large number of bacteriophages would be needed to cope with the variety of pathogens encountered in Nature. Secondly, it was discovered that bacteriophage added to a culture does not lyse all the bacteria present: a few resistant organisms survive and multiply, and the new culture which grows out consists of organisms resistant to the bacteriophage. For these reasons bacteriophage never proved itself as a therapeutic or preventive agent, and its use has been confined mainly to the laboratory, where the specificity of its action has been a great asset. As bacteriophages will attack only closely related strains, they are widely used for typing Bacteria responsible for infections.

Meanwhile the place of bacteriophage in Nature has remained rather obscure. What are the origins of specific bacteriophages? Why should almost every serological type of bacterium apparently have a corresponding specific bacteriophage waiting to attack it? Has bacteriophage any function at all in the natural history of bacteria? Elsewhere in our present issue Dr. L. F. HEWITT proposes answers to these questions. It is, as he says, a common observation that bacteriophages which are specific to one serological type of organism can often be adapted to lyse organisms of a different type, on which at first they have no effect. But now he reports that bacteriophages can be adapted to attack not only a different serological type but also a different species: for he has found that staphylococcus bacteriophage can be made to act on diphtheria bacilli. If this interaction between different species turns out to be a general phenomenon, the problem of the origin of a variety of specific bacteriophages will disappear; for we need postulate only the existence of a single bacteriophage, or small group of bacteriophages, to understand how by adaptation the whole multitude of specific bacteriophages may be evolved. From this Dr. HEWITT goes on to suggest that bacteriophages play an important part in Nature in controlling the evolution of bacteria and their virulence, and hence the spread of epidemics. A specific bacteriophage, by lysing all the organisms in a susceptible culture except the few mutants which are resistant, exerts a potent, selective action. The resistant mutants often have quite different characters from the parent strain, and in a single subculture the properties of a strain may therefore be entirely altered: for example, a completely avirulent diphtheria strain can become virulent and toxigenic. The intervention of the bacteriophage may thus be said to speed up, very greatly, the slow processes of natural selection.

Quite a high proportion of bacteria usually carry a latent bacteriophage, which does not seem to do them any harm but is capable of lysing other strains with which it comes in contact. Thus cultivation together of a phage-carrying strain and a susceptible strain can result in modification of the susceptible strain through selection of the resistant mutants which survive the action of the phage. This has been demonstrated in mixed cultures in the laboratory, and a similar process might presumably occur in infected patients. As it must be comparatively rare for a patient to be infected with two strains of the same bacterial species—one carrying phage and the other susceptible to its action—the possible modification of strains in this way has not seemed very important. But if, as Dr. HEWITT claims, staphylococcus bacteriophages can be readily adapted to lyse diphtheria bacilli, a new significance will be attached to the coincident infection of a patient with two different species of bacteria. The bacteriophage from one species, if it is adapted during the infective process to attack the other, could modify its properties by the selection of resistant mutants. The infective agent passed on to the next patient would then be different from the primary infection, and, if the resistant mutant selected happened to differ considerably, the change in the nature of the infection might be dramatic. The plagues which have in the past suddenly flared up and devastated large populations may have originated in some such selective process; and bacteriophage, instead of being regarded as a mere academic toy, must be suspected of possibly very sinister activities in epidemiology. Such speculation apart, Dr. HEWITT's evidence suggests that it has had, and still has, an important rôle in bacterial evolution.

Annotations

OVERCROWDING IN PRISON

THERE can be worse things in prison than iron bars, and sleeping three to a cell is probably one of them. In its seventh report the Select Committee on Estimates[1] deplores that 4500 men in our prisons are sleeping in this overcrowded way. The reason is not far to seek, for the prison population has now risen to over 25,000 men and women—twice as many as before the war. It is ironical that this increase is in part due to the Criminal Justice Act of 1948, which, with the aim of reforming people and not merely deterring them from crime, permits longer sentences. The additional responsibilities which the Act imposes have unfortunately fallen on the prison organisation at a time when it still has not made good war-time deficiencies in accommodation and staff, and the problems of overcrowding are aggravated by those of understaffing. Not only are there too many prisoners but there are too few warders. As a result the prisoners spend long hours of boredom and near idleness in their cells while the warders habitually put in overtime. The committee dislikes both the short working week of the prisoners—sometimes as short as 22 hours—and the long working week of the warders; it thinks that overtime in the long run is neither economical nor efficient. Much of the indiscipline, everyone agrees, is due to a comparatively small group of prisoners. The worst prisoners are not usually the worst criminals, and the committee urges the Prison Commissioners to give high priority to building a separate prison or prisons where these psychopathic trouble-makers could be not only segregated but also studied and treated.

Overcrowding brings problems of health as well as discipline, and the committee is especially concerned at the increased risk of infection, particularly of tuberculosis. Some arrangements have been made to examine prisoners by mass-radiography units; but the initiative is left to the senior medical officer in each prison, and the committee recommends that the Director of Prison Medical Services should approach the Ministry of Health to ensure that prisoners get their fair share of the services of these units. The prison medical service, like the other branches, is understaffed. Instead of 52 full-time doctors, it has only 42; and few recruits come forward, for the salaries are unattractive. The committee particularly regrets that it is no longer possible to produce a medical and psychiatric report of each boy and girl who passes through the borstal allocation centre, and urges an early return to this pre-war custom.

MYXOMATOSIS AND RABBITS

IN the past fifteen months an artificially induced epizoötic has killed many millions of rabbits in Australia, thus demonstrating for the first time that a pathogenic agent can be successfully put to work against a mammalian pest.[2] Myxoma virus, which may be related to the pox group of viruses, has a species of Brazilian "rabbit" as its natural host, and it was first recognised in laboratory animals by Dr. H. B. Aragão, who also suggested its use in biological control. The work started by Sir Charles Martin in 1933 at Cambridge showed that the disease was highly pathogenic for wild and domestic rabbits, but was harmless for all domestic animals and for most of the native fauna of Australia, as well as for the imported European hare. Fears that the virus might be the cause of serious infections in man have also proved unfounded. Myxoma virus thus combines extreme virulence for one animal pest with almost complete avirulence for most other creatures, and it was therefore an ideal pathogen to use in attempts at biological control.

Field trials carried out before the late war in semi-arid pastoral areas were inconclusive, but they did show that the virus was transmitted among rabbits by the stickfast flea, whose limited mobility made it a poor vector. Some of the many ecological difficulties were soon encountered; for example, it was impossible to establish and spread the disease where foxes were lying in wait to pick off the first generations of lazy infected rabbits. After the war the Commonwealth Scientific and Industrial Research Organisation decided to re-examine the possibilities of controlling the increasingly serious rabbit menace with myxoma virus, and between May and November, 1950, the virus was released seven times in the Murray valley. The immediate results were [illegible]: the disease had no appreciable eff[illegible] of rabbits. In December, however, the disease suddenly flared up at one of the infected places, and soon reports came from many other areas, including a place on the Darling river nearly 400 miles from the nearest known point of infection. The wide dispersal of the virus and the intense local spread produced a remarkable epizoötic within the next two or three months, and it was thought that mosquitoes, moving under their own power or carried by high-level winds, were responsible. Nothing else could explain the isolated outbreaks along the southern margins of the epidemic area in Victoria and in South Australia, nor an isolated outbreak almost in the centre of the continent. In the new year the epizoötic gained momentum, and by February, 1951, an area of 1000 square miles was involved. The disease spread at remarkable speed through the rabbit population and killed 90% of them. River courses, creeks, and swamps were most heavily involved, suggesting once again that water-breeding vectors were essential to spread. In such a large area, however, geographical conditions varied enormously; in the Murray valley, for example, only those rabbits within a few hundred yards of the water's edge were killed, whereas in south-east Queensland the disease was unbounded, and it was possible to drive for a day or more through country that had previously been swarming with rabbits and see only a few isolated survivors.

When the trials began it was known that myxoma virus could be transmitted by two species of flea and by several species of mosquito, but little was known about their performance in the field. It was found that transmission was almost certainly mechanical and that any blood-sucking arthropod was a potential vector. The epidemiology of the disease, and hence its practical value in biological control, is largely influenced by the ecology and habits of vectors, the strength of their preference for rabbit blood, and the length of time for which they are about in great numbers. In such a vast and varied area it was likely that different vectors would have local predominance; in the Murray valley, for example, *Culex annulirostris* was a principal vector, whereas on the Victorian coast and the off-shore islands *Aedes camptorhynchus* was the most important. During the winter months of 1951 the disease continued to smoulder, and ectoparasites may have ensured the persistence which was necessary to the success of the scheme. In the summer of 1951–52 a closer study was made of the various vectors, and *Anopheles annulipes*, which spends the day in the rabbit warrens, was found to have played a predominant part. This third phase of the epizoötic has developed mainly in areas not involved before, and attacks were most intense where suitable anopheles breeding-grounds were plentiful. In the Murray valley during 1951–52 this mosquito forestalled in time and outstripped in range the culicine vector of 1950, so that, instead of the disease being confined to a narrow strip along the breeding-waters, it now spread for as many miles as it had hundreds of yards during the previous summer. These entomological studies have now covered a full cycle of the seasons, and the broad pattern of the ecology of the mosquito fauna shows a fairly clear succession of species, each becoming dominant as larval and adult habitats change in nature and extent.

[2] Ratcliffe, F. N., Myers, K., Fennessy, B. V., Calaby, J. H. *Nature, Lond.* 1952, 170, 7.

What of the practical results so far achieved in the control of the rabbit pest in Australia? What is likely to be the ultimate effect of introducing myxomatosis into the country? Ratcliffe and his colleagues[2] approach these questions cautiously, but in one sample area of 100 square miles, where 64,000 acres were classed as heavily infected before the epizoötic, only 640 acres remained so after it. In large parts of South Australia, Victoria, and New South Wales the number of rabbits is now one tenth or less of the 1950 figure. Thousands of farms have had their land cleared of rabbits, with an obvious and immediate increase in pasture growth and stock-carrying capacity. When the epizoötic took place, rabbits were very numerous, even for Australia, and the seasons were favourable for the virus vectors; in these circumstances the mortality was high and it is probable that tens of millions of rabbits died. It is reasonably certain that myxomatosis is now permanently established in Australia: and it may soon become more uniformly distributed throughout the rabbit population, and thus be able to spread more rapidly under favourable local conditions. But a final judgment is not yet possible. A natural process of adjustment between parasite and host may take place either by the emergence of virus strains of altered virulence or by the development of resistant generations of rabbits, or by both. These possibilities are being examined experimentally and there is already evidence that recovery is commoner in the field than in the laboratory, where a 100% mortality has been the rule.

This interesting experiment is of immense practical importance, and its Australian designers are alive to the many ecological and epidemiological opportunities that it affords.

LARYNGEAL SPASM

THE larynx has been called the watchdog of the respiratory tract. Perhaps it might be better named the watchdog of the patient, because laryngeal closure—probably as a protective response—may follow harmful stimulation of almost any part of the body. The risk of such spasm has always haunted the anæsthetist. While on the one hand it protects patients from inhalation of vomit, on the other it interferes with anæsthesia by making it difficult to introduce irritant vapours such as ether into the lungs, and by rendering many operations more or less impossible under light anæsthesia. Whether the spasm by itself can cause the death of a patient is a question which anæsthetists have long discussed among themselves. It is doubtful whether death from this cause alone ever takes place in ordinary clinical practice; for when the anoxia and carbon dioxide accumulation reaches a certain point the patient gasps once or twice and takes in enough air to get a grip on life again.

The treatment of laryngeal spasm consists primarily in removing the causal stimulus. One of the first lessons learnt by the young anæsthetist is that spasm of this sort during induction of anæsthesia with ether is best treated by weakening the ether vapour inhaled and starting again, rather than by pouring more ether on the mask. Similarly laryngeal spasm in the middle of an abdominal operation is an indication for a pause in the surgical work before, and not after, an attempt to deepen the anæsthesia. The use of muscle relaxants to treat laryngeal spasm in the presence of its causal stimuli can be very dangerous, because the respiratory muscles are paralysed at the same time as the laryngeal spasm relaxes. This method should be adopted only by the most experienced anæsthetists. Artificial respiration by compression of the chest is ineffective against severe laryngeal spasm; for the expiratory muscles are usually in spasm too. Even the worst spasm, however, quickly responds to removal of the ether mask. Then the lungs can be inflated with oxygen from an oxygen-filled bag, which is gently squeezed; or, failing oxygen, air can be used. Very occasionally the larynx may have to be exposed and a small-bore, smooth-tipped, firm catheter gently inserted between the cords—great care being taken to avoid damage to the larynx. Drugs have little, if any, place in the treatment of this condition, which is primarily one of motor reflex activity.

REACTIONS AFTER VITAMIN-B INJECTION

THE vitamins of the B group are the ones most frequently given by injection. Untoward effects after such injections are uncommon, but two fatal reactions have been recorded; in one case[1] thiamine had been given intramuscularly, and in the other[2] intravenously. Other less severe reactions, including circulatory collapse, have occurred not only with thiamine but with other members of the group. Two types of major reaction following the injection of thiamine have been described.[3] In one a condition resembling anaphylactic shock may occur in sensitised persons, usually after a long course of symptomless injections. The other less dramatic type produces symptoms like those of thyroid overdosage—excitement, tremor, palpitation, giddiness, and insomnia. Intradermal tests have shown sensitivity to the vitamin in both types of reaction.[4–6]

Chitwood and Moore[7] have lately reported what they regard as the first case of severe anaphylactic shock after an intravenous injection of vitamin-B complex. Circulatory collapse has also been reported after intravenous nicotinic acid[8 9] and folic acid.[10] But most of the reactions seem to have followed the use of thiamine.[11] Weigand[12] analysed the reports of 143 physicians who gave thiamine by injection and found 179 cases in which there was a reaction, but only 17 were described as serious. The less pronounced reactions might, of course, be easily overlooked. Sensitivity to thiamine and other members of the group can be acquired; in all the reported cases hypersensitivity developed only after repeated symptomless injections, with the notable exception of nicotinic acid which caused circulatory collapse in 2 patients immediately after the first injection.[9 10]

Acute vitamin-B deficiencies are rare in this country, and the risks arising from injection of vitamin B must be taken into account when considering its advantages. Obviously there will be a stronger case in its favour when absorption by mouth is deficient. As a precautionary measure skin tests may be carried out, but it has been said that thiamine is an obligate weal-producing agent[13]

and if this is so a positive intradermal test would not be conclusive proof of individual sensitivity. In most cases hypersensitiveness develops suddenly during a course of injections; and the best form of prophylaxis at present seems to be to question the patient thoroughly about the effect of previous injections before giving him another one.

FLAGELLA FOR SPIROCHÆTES?

WHEN the name "spirochæte" was first used by Ehrenberg in 1833, it was applied to a large motile organism found in water. Nowadays the term denotes a group of organisms which are motile, spirally twisted, and flexible. Their structure has always aroused interest, and the information amassed about them seems to support the opinion expressed by Dobell[1] forty years ago that the group are most closely allied to bacteria. Thus, while they differ from protozoa in many ways, there is only one respect in which they do not conform to general bacterial characteristics—namely, their motility in the apparent absence of flagella. All the four genera (spirochæta, cristispira, treponema, leptospira) which are generally accepted as spirochætes possess well-defined group features. They contain no colouring matter or nucleus, they divide transversely either by simple or multiple division, and no evidence of any sexual reproductive apparatus has ever been demonstrated. Though they are supposed to have no flagella they can move in a forward or backward direction.

With the coming of the electron microscope this question of spirochætal flagella has been reopened, for some investigators claim to have seen at least some spirochætes with these appendages.[2,3] The latest evidence of the existence of spirochætal flagella includes photographs taken with the electron microscope by the shadow-casting technique using chromium.[4] The organisms studied included cultured strains of Nichol and Reiter's treponemes, and the authors maintain that the flagella are definite structures and not fragments of the spirochætes. Flagella are described as being attached subterminally, but, while the basal granules seen in bacterial flagella have not been demonstrated, a slight enlargement of the body of the organism was noted where the tuft of flagella emerges. Knaysi[5] refers to "flagellum-like extensions," but quotes Dyar as saying in 1947 that in a free-living spirochæte resembling *Spirochæta plicatilis* it was not possible to demonstrate these flagellum-like extensions with either the optical or the electron microscope.

Bradfield and Cater,[6] in an interesting report on a study of leptospira, treponema, and cristispira by electron microscopy at 70 kV, suggest that spirochætes consist of a central protoplasmic core around which is wound a bundle of fibres, the whole resembling a two-strand flex. In some cases a cell membrane envelops this structure, while in others the bundle of fibres lies outside the membrane. "Chemical dissection" of the organisms by trypsin digestion partially or completely removes the cell membrane, while the bundle of fibres is either left intact or falls apart into its components; the central protoplasmic core remains unaffected. In the experience of these workers when spirochætes are intact or undamaged by preparative techniques, they *never* possess flagella. There is indirect evidence that the fibres are contractile, and Bradfield and Cater suggest that these structures do not have a skeletal function. If this is the case it could account for the changes in shape and possibly the movements of the organisms.

It is clear that at the moment there is no agreement about the reality or otherwise of spirochætal flagella. Nor, indeed, have we yet heard of any final settlement of the larger question whether flagella really supply the motive power of the types of organism which everybody has recognised as flagellate. Working with proteus and salmonella, Pijper has satisfied himself that they remain quite mobile when deprived of their flagella; and much has now been written on this fascinating subject.[7]

THE BIOCHEMICAL CONGRESS

THE second International Congress of Biochemistry met in Paris, at the invitation of the Société de Chimie Biologique, from July 21 to 28. The preceding congress of this kind took place in Cambridge in 1949, and the third congress is to be in Brussels in 1955. The Paris congress attracted over 2000 members of more than forty nationalities, including Russians, Poles, and Yugoslavs, and more than 800 papers were read during the week.

The inaugural ceremony, at which the members were welcomed by Prof. Gabriel Bertrand (president d'honneur), Doyen René Fabre (president of the congress), and Prof. Claude Fromageot (president of the executive committee), was held in the great amphitheatre of the Sorbonne, and the various discussions were held in its lecture-theatres—many meetings, of course, being concurrent. The major events included four special lectures given in the great amphitheatre, by Prof. J. N. Davidson (University of Glasgow), A. I. Oparine (Bach Institute of Biochemistry, U.S.S.R.), Prof. S. Ochoa (College of Medicine, New York University), and Prof. R. Linderstrom-Lang (Carlsberg Laboratories, Copenhagen): their respective subjects were nucleoproteins and tissue growth, the changes in enzymic action in plant cells under the influence of external factors, carbon dioxide fixation in plants and animals, and proteins and enzymes. Thirty-one separate sections of the congress considered mineral elements, lipids, amino-acids and proteins, nucleoproteins, pigments, fat-soluble vitamins—and twenty other topics. In addition there were seven symposia devoted to biochemistry of hæmopoiesis, the biogenesis of proteins, the tricarboxylic acid cycle, protein hormones and hormones derived from proteins, the metabolism of micro-organisms, the mode of action of antibiotics, and the biochemistry of sterols. In each symposium there were about ten "reports," occupying about an hour each, and a large number of "communications." The gathering was remarkable in bringing together so many active investigators from so many lands, and if it was a little disappointing in that it did not seem to evoke pronouncements on any new and revolutionary discoveries, it nevertheless demonstrated very clearly the enormous progress made in the last few years in understanding details of biochemical mechanisms. Biochemical knowledge is extending very rapidly deep into the intercellular reactions, and the use of radioisotopes has given biochemists a penetrating tool.

The Société de Chimie Biologique has made a very useful contribution to the advancement of biochemistry by providing such good conditions for the meetings and discussions, formal and informal. The opportunity for such concentrated cross-reference to other fields is invaluable to every specialist.

H.R.H. the DUKE OF EDINBURGH has accepted the honorary fellowship of the Royal College of Physicians of London.

Mr. E. R. GARNETT PASSE, aural surgeon to Wembley Hospital, died in London on Aug. 1.

Before our Time

RAMÓN y CAJAL

The First Centenary of his Birth *

JOSEPH TRUETA
M.D. Barcelona, Hon. D.Sc. Oxfd
NUFFIELD PROFESSOR OF ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF OXFORD

ON May 1, 1852, Santiago Ramón y Cajal was born in Petilla of Aragon, the eldest of a modest family from the foot-hills of the Pyrénées in the area whose political and cultural centre was the town of Huesca. His father's family name indicates the Pyrenean roots of his ancestors, Ramón being a local patronymic and the name of many princes in the lands extending from the Garonne to the Ebro rivers. Cajal depicts his grandfather as a fair mountaineer who at 75 was a strong and agile giant. Casasús, the family name of his paternal grandmother, is again typical of the Catalano-Aragonese land. From his mother's side he inherited the name of Cajal, Aragonese adaptation of the Catalano-Provençal *caxal* or molar tooth.

The land from which his family came, and that in which he spent his early life, has forged many strong and resolute men: strength and resolution are in fact the two more outstanding characteristics of the Aragonese race. From the southern side of the Pyrénées, in the area extending from Jaca to the Mediterranean, came the medieval soldiers known as *almogavers* who left such a mark of their passage across the lands of Sicily and Greece in the 13th and 14th centuries. But, side by side with these fighting characteristics, other more precious if less striking qualities form part of the Aragonese nature; I refer to their sincerity and their simple and modest nobility. As will be seen later, all these features are apparent in Cajal.

The two best examples of human activity he saw in his infancy and early childhood were that of his father, a village surgeon later a qualified doctor in medicine, and that of his mother's brother, a home weaver, in whose home in Jaca he lived for some time.

Up to his 15th year Cajal was more of an *almogaver* than a student. In the places where his father successively worked young Cajal became the head of the children's gang which terrorised neighbours and irritated authorities; and on one occasion this landed him in prison for four days. He repeatedly failed in his studies both in Jaca and in Huesca, and his authoritarian father thought to punish him by placing him as apprentice to a shoemaker and later to a barber. During these years his only other activity, alternating with his violent enterprises, was drawing. He had decided to make drawing and painting his profession, and it was only because of his father's iron will and lack of artistic sense that he was not forever lost to the world of science. Even as a scientist he never forgot his early inclination for designing, and the fidelity of his pen is evident in the drawings illustrating his early histological works.

In contrast with this rapid physical and artistic development, his intellectual awakening was very slow. Latin was to him an obstacle much harder to surmount than the highest stone wall or the more inaccessible mountain. In his own phrase, he regarded Latin as "a profuse shower of rules desauthorised by infinite numbers of exceptions." But if reading his school books on Latin, algebra, and physics bored him terribly, he soon developed an insatiable hunger for the literature of adventure, which (as he tells us in his autobiography) agreed with his desire to be known and famous and with his decision to strengthen his will by controlling his emotions. At 12 he read a Spanish translation of *Robinson Crusoe*, and because it hints at some of the reasons for his later passion for research I shall reproduce in his own words the impression this book made upon him:

> "Robinson Crusoe (which I read again and again with true delight) revealed to me the sovereign power of man confronted with nature. But what impressed me most was the noble pride of him who, owing to his own efforts discovers a wild isle full of traps and dangers capable of becoming, thanks to the miracles of will power and intelligent efforts, a delightful paradise. What a magnificent triumph it must be to explore virgin land with the landscape animated with strange flora and fauna as if it had been expressly created as a prize to the extreme heroism of its discoverer."

An associate of Cajal's in his early days, Dr. R. Solillás, wrote that the boy was so convinced of the reality of his dreams that he organised an expedition to an island on a neighbouring river and managed to make his friends believe that the wild animals and all the rest of his fantasy were real. In considering his later work we should not forget this powerful imagination, which made his scientific contributions so revolutionary, and so personal, while his cold realism made them so reliable. He was in fact one of those Spaniards who are endowed with this strange combination of realism and imagination—who fuse in themselves the opposite natures of Don Quixote and Sancho Panza. Perhaps the purpose of Cervantes in portraying the heroes of his immortal novel was to split into two the human features that he considered indescribable when woven together into a single human nature. Goya, the Aragonese painter, shows equally this apparent contradiction. The realism of such men is saved from crudity or hardness not only by their creative imagination but often also by a kind of poetic halo.

THE YOUNG DOCTOR

Having finished his preliminary studies, he entered the Medical School of Zaragoza where his father had been appointed prosector in anatomy. With his father's help he mastered the complexity of descriptive and topographic anatomy, and his ability to design anatomical preparations made him popular with some of his teachers.

Qualification was followed by service into the army as a medical lieutenant, and soon he was sent to Cuba where the nationalist guerrillas, and particularly the yellow fever and malaria, were causing havoc among the Spanish troops. Full of patriotic enthusiasm, he joined an expeditionary force which landed in La Habana, and was immediately sent to an advanced medical post where the two previous medical officers had died of malaria. Soon he became extremely ill, and after remaining in this post for several months he was repatriated an emaciated and defeated man suffering from jaundice and anæmia. It is understandable that he complained of the way in which the war had been conducted; he thought that the war could have been prevented by following the example of England—"the indisputable master in the arts of politics, always attentive to learn from reality."

---

* Paper read to the Osler Club on May 9, 1952.

As soon as he had recovered sufficiently he went back to Zaragoza as assistant in the department of anatomy, with an annual salary of 1000 pesetas (about £30 at that time).

After this Cuban adventure his health was precarious, and two or three years later he suffered two severe hæmoptyses while sitting in a café in Zaragoza. It was then found that in Cuba he had contracted tuberculosis as well as malaria. Fortunately for Cajal, and for science, his strong nature reacted favourably while among the forests of the Pyrenees, and after about a year he was back at his work in anatomy in Zaragoza. He married shortly afterwards a beautiful girl, with large green eyes, who was to be his life companion. Meanwhile he was preparing himself to enter the academic life.

ACQUIRING A CHAIR

Here a word is necessary about the strange procedure traditionally followed in Spain to fill the professorial chairs.

The competitors go through a series of oral, written, and technical exercises and tests of their ability, *not unlike those* undertaken in England by candidates for the F.R.C.S. or M.R.C.P. What is unusual, however, is the direct competition among the candidates, who are invited to criticise the clinical and scientific exercises of their opponents and to demonstrate any weakness these may have shown. This method of investigation is no doubt based on the old procedures for inquiry into religious matters.

The competition ends, in theory at least, in the most brilliant among the candidates being elected to the post. But unfortunately a technique that may be valuable for assessing the basic knowledge of a doctor of 30, whose experience and wisdom lie in the future, is nearly disastrous to a man of 50 or more, whose experience and wisdom have been *long acquired. The effect of the Spanish method of selection* is that in Spain the ambitious and capable young man may begin competing for professorial posts a few years after qualifying, and with good luck he can become professor in a medical school at 30 or 32. If, instead, he spends his time in acquiring sound medical knowledge, or in research requiring much reading and thought, his name may be respected and even famous at 50; but by that time he will hardly dare to compete for a chair against youngsters saturated with bibliographical references, who have nothing to lose, not even reputation.

Cajal's first attempt to become a professor was in 1879 when he was only 27; he competed for the chair of Zaragoza and he failed. During his short visit to Madrid he saw some histological preparations by Maestre de San Juan, the earliest histologist in Spain, and he became so enthusiastic about this method of observation that he bought himself a Verick microscope and several books on micro-techniques and histology. He also subscribed to the *Quarterly Journal of Microscopical Science* and to a French journal.

Having carefully analysed the weak spots responsible for his failure in the competition, he presently competed for the chair of anatomy of Granada; but an "official" candidate was preferred. At his next attempt, this time at Valencia in 1883, he was appointed professor. Thus in his 31st year he finally became free from the limiting compulsion of the "oppositions" and was able to concentrate on microscopy. While still in Zaragoza in 1880 he had published his first paper on the histology of the nervous system, studying the neuromuscular synapse, and later in Valencia prepared for publication his famous book *Manual of Normal Histology and Microscopical Technique.*

BARCELONA AND MADRID

In 1887 the new chairs of histology in Barcelona and Zaragoza were to be filled, this time by selecting an applicant professor from another university, and Cajal was appointed to Barcelona. There he organised his laboratory in the old Hospital de la Santa Creu; it was the same place where Antoni de Gimbernat devised his operation for hernia before coming to London to discuss the merits of his methods with John Hunter in 1776. In this hospital I learned to become a surgeon more than thirty years after the appointment of the great histologist.

In 1888 he entered what later he called the greatest year of his life. The International Exhibition of Barcelona was stimulating the growing activities of the Barcelonians, of whom he was one of the more illustrious. He presented his micro-preparations in the exhibition and was awarded a gold medal. He had been told of the silver method used by Camilo Golgi since 1875 to dye nervous structures and he began using and adapting this method to explore the unknown worlds of the cerebellum and then the cerebrum. The Barcelona *Gaceta Médica Catalana* appeared with several of the greatest contributions by Cajal; in 1888 he put forward the main facts supporting the anatomico-physiological laws of the nervous cells of the grey matter. He also described the "fine axons" and published his earliest work on the retina. From now on works appeared in an uninterrupted flow. His name became known abroad and his collaboration was sought first in Germany and soon in other countries. In 1892 the chair of histology in the University of Madrid became vacant and Cajal was appointed professor, after going through a new competition. In Madrid he was able to begin the second part of his life-work and that by which his stature as a teacher must be measured. This was the creation of his school of microscopical anatomy.

DAYS OF HONOUR

Cajal endured from early times the pleasant but disturbing interferences brought about by distinction and fame. In February, 1894, the Royal Society of London invited him to deliver a Croonian lecture and on March 8 he read his paper on the Fine Structure of the Nervous Centres which appeared in the *Proceedings of the Royal Society.* Sherrington gave him hospitality in his home, and Cambridge gave him a SC.D. hon. causa. In 1899, one year after the defeat of Spain by the United States, he lectured in the victorious country and was made a D.SC. hon. causa of Clark University, Worcester. In 1900 he was awarded the International Prize at the International Congress of Medicine in Paris. In 1904 the Helmhoth gold medal was presented to him by the Royal Academy of Sciences in Berlin, and in 1906 he and Golgi received the Nobel Prize. From then until he died in 1934 Cajal was honoured by universities, academies, and medical societies as few people had ever been. In 1922, having reached his 70th anniversary, he retired from his chair but continued the direction of the Institute that had been created in 1898. At his retirement a book was published in his honour.

On Oct. 17, 1934, Cajal died in his 82nd year, surrounded by his sons and by his pupils and friends Tello, Illera, Carro, Yagüe, and Hernando. The social and political disorders of the days immediately following the abortive revolution of the "6th of October" caused the funeral of this great man to pass unnoticed by the authorities, but he was accompanied to his resting-place by the sympathy, and in many cases the love, of all in Spain who cared for the progress of science.

THE TAUGHT AND THE TEACHING

There is no better way of judging the merits of a master than to consider the work of his pupils, and I must refer at least to some of those who owed Cajal their histological education and have been known abroad, particularly in the Anglo-Saxon world.

J. F. Tello was considered by Cajal a personal friend apart from being his senior pupil. P. Del Rio Hortega after leaving Madrid in 1936, worked for three years in Oxford before moving to Buenos Aires, where he died a few years ago. Lorente de No established himself in New York for many years. F. de Castro is still in Madrid and I understand is now only partially working in research. G. R. Lafora is back in Madrid after teaching in Mexico for several years. N. Achúcarro died years ago.

If ever a civil war can bring anything but sorrow, perhaps we may detect, after fifteen years, some benefit in the Spanish war having disseminated throughout the world some of the pupils whom Cajal moulded by his example and daily teaching. They sowed in fertile soils the seeds he had put in their hands.

Even to index Cajal's histological works is a strenuous task. For nearly fifty years he worked with a passion difficult to parallel. Ten books in Spanish, four in German, two in French, and two in English, with 263 monographs and papers, constitute a volume hardly ever equalled by any scientist in any field. To analyse the nature of his work would be yet harder, and here it must suffice to say that from his early paper published in Barcelona in 1888 his contributions were continuous. In that paper he had described for the first time the arborisation of the endings of the cylindro-axons. The structure of the cerebellum was likewise described in 1888 in the *Gaceta Médica Catalana* where for the first time he formulated the theory of the neurons which forms the anatomo-physiological code of the nervous system. In the same journal and in the same year we find his accounts of the structure of the spinal cord and of the method of the double silver impregnation. In 1891 he produced his work on the retina and his description of the neuroglia of the sympathetic ganglia. In 1905 came his early work on the degeneration and regeneration of the peripheral nerves.

It is, I think, impressive that so many of Cajal's works have resisted, and are still resisting, the assaults of modern research. He removed the unfounded theories of Gerlach and Golgi on the transmission of the nerve impulse, and what he put in their place is still standing after 70 years. That is the measure of his calibre as an accurate investigator.

INFLUENCE ON CONTEMPORARY SPANISH THOUGHT

The awakening of interest in the three laboratory branches of biology (bacteriology, physiology, and histology) took place in Spain almost at the same time. The requisite circumstances arose about the last quarter of the 19th century.

Fortunately for Spain three notable men decided almost simultaneously to explore the three different fields. Jaume Ferran took bacteriology and immunity as his province and from his institute in Barcelona he introduced active immunisation against cholera in 1885, when Cajal was professor in Valencia. Ferran's method was tested for the first time during the epidemic at Valencia, after Cajal had advised the authorities to try the new method; but economic difficulties and lack of official support, among other causes, prevented consolidation of his work. Ramón Turró, like Pasteur a veterinarian, was responsible for creating the Institute of Biology at Barcelona, mainly devoted to the study of physiology; like Cajal's, his school came to have pupils scattered throughout the world. But after so many labours, of these three schools only that of Cajal has survived the civil war.

Cajal, Ferran, and Turró appeared during the twenty-five years preceding the Spanish-American war of 1898. A long period of internal peace gave the conditions necessary for developing scientific research—those conditions that are basic to the England whose example Cajal so much admired. It also tended towards acceptance of the English method of building a Cambridge in front of every Oxford, to reduce the risks of exclusiveness —another of the essentials for modern science. In this respect Cajal also had a clear view of what was desirable.

At the end of his days he could look back with satisfaction to the many unknown islands he had explored for the first time with the help of a microscope. He must have been happy in seeing the dream of his youth fulfilled; that of becoming an explorer and a hero—a Robinson Crusoe of modern science.

Special Articles

CLINICAL RESEARCH IN THE UNITED STATES

THE following summaries of some of the papers read at three meetings in Atlantic City this summer will give readers a picture of some of the clinical research being done in the U.S.A.

American Federation for Clinical Research

Antagonisms between Heparin and Adrenocortical Eosinopenia in vitro and in vivo.—R. C. MUEHRCKE, J. L. LEWIS, J. PETERS, and R. M. KARK (Chicago) showed that cortisone and other 17-hydroxy compounds will produce lysis of eosinophils in sterile defibrinated blood in the test-tube. This effect is blocked by heparin, oxalate, or resins that remove calcium from the blood. Large doses of heparin injected at the same time as A.C.T.H. (in vivo) also block eosinolysis. In test-tube blood, after eosinolysis, they noted many degenerate eosinophils on smeared slides. In vivo, they believe, these cells are sequestrated and removed by the lungs. The confirmatory evidence is the different eosinophil levels in pulmonary-artery blood (taken by catheter) and in arterial blood. They demonstrated that adrenaline acts not via the pituitary but peripherally in the presence of cortical hormones; and they showed in five patients who had undergone complete bilateral adrenalectomy that injections of adrenaline caused the eosinophils to disappear from the blood. These do not seem to be direct effects on the eosinophils, for in vitro adrenaline does not potentiate the eosinolytic action of cortisone.

Deuterium Oxide and Total Body-water in Œdematous Subjects.—W. W. HURST and F. R. SCHEMM (Great Falls, Montana) found that in the estimation of total body-water oral administration of deuterium oxide gave much the same result as intravenous injection. In 7 œdematous patients they found that the distribution of deuterium oxide in œdema, pleural, and ascitic fluid was complete at 15 hours. Total body-water was calculated after correction for urinary loss of deuterium. After diuresis, the patients' total body-water was again measured and a very close correlation was noted between the calculated loss of body-water and the measured urinary output. The conclusion reached was that the oral method is reliable provided a long enough time is allowed for distribution of the deuterium oxide and a correction is made for urinary loss of deuterium.

Absorption of Radioactive Iron in Normal, Anæmic, and Hæmochromatotic Subjects.—R. B. CHODUS and J. F. ROSS (Boston, Mass.) gave radioactive iron (Fe^{59}) to healthy people and to patients with iron-deficiency anæmia and with hæmochromatosis. They measured the fæcal excretion (taken as representing unabsorbed iron) and the radio-iron incorporated into hæmoglobin, assuming that the remainder was deposited in the body's iron stores. The percentage partition of ingested iron was found to be as follows:

	Fæces (%)	*Hæmoglobin* (%)	*Stored* (%)
In healthy people ..	66–90	1–10	1–25
In iron-deficiency anæmia	40–60	40–60	4–7
In hæmochromatosis ..	84–98	0·5–11	0–5

Chodus and Ross interpreted these data as indicating that the absorption of iron is greater than normal in iron deficiency, whereas in well-developed hæmochromatosis it is less than normal. Their conclusion regarding hæmochromatosis was based on long-established cases and could only be accepted if the same findings were obtained in early hæmochromatosis.

Treatment of Barbiturate Poisoning by Hæmodialysis.—W. P. WALSH, L. H. KYLE, P. D. DOOLAN, and H. JAGHERS (Washington, D.C.) showed that in experimental barbiturate intoxication 20–30 times as much barbiturate as the normal kidney excreted could be removed from the body by dialysis with an artificial kidney. They reported 2 severe cases successfully treated by hæmodialysis, and suggested that this is the best treatment to adopt for such patients.

Ascorbic-acid Deficiency in Pernicious Anæmia.—R. O. WALLERSTEIN, J. W. HARRIS, and G. T. GABUZDA, jun. (Boston, Mass.), estimated the vitamin-C levels in peripheral blood or bone-marrow buffy coats from 21 patients with untreated pernicious anæmia and 2 with nutritional macrocytic anæmia. No vitamin C was found in 20 of the 23 patients. None of the patients had any clinical evidence of scurvy. Six patients were studied intensively. Two were given 1 mg. of vitamin C daily for 11 days; in one the reticulocytes rose to 7·7% but there was no concomitant rise in hæmoglobin or evidence of marrow maturation; in the other there was no hæmatological response. Two patients were given B_{12} without vitamin C, and then vitamin C was added later; 1 had a mild reticulocytosis, followed by a second greater reticulocyte response to the B_{12} but no secondary response on the addition of vitamin C. Finally, 2 patients were given folic acid, producing a mild reticulocyte response, after which they were given vitamin C and there was a second response. The conclusion drawn from these observations was that there is a severe biochemical vitamin-C deficiency in pernicious anæmia, and the Boston team believe that vitamin C may play an adjuvant rôle in hæmopoiesis, probably by enhancing the production of citrovorum factor.

American Society for Clinical Investigation

The Thyroid Hormonal Pool in Man and Dog.—A. STONE FREEDBERG, LEONARD WOLSKY, GEORGE S. KURLAND, and MILTON W. NAMOLSKY (Boston, Mass.) infused thyroid hormone labelled with I^{131}, obtained from the blood of patients who had been treated with I^{131}, into euthyroid, hyperthyroid, and myxœdematous patients. Studies of the turnover rate of the hormone and the size of the diffusable hormonal pool indicated that in thyrotoxicosis the total pool was about three times, and the turnover rate about four times, as great as in the euthyroid state. The myxœdematous patients had a very small pool and a slow turnover of the tagged hormone. In further studies, euthyroid dogs were infused with euthyroid and thyrotoxic tagged hormone, and the turnover rates of the thyrotoxic hormone were about twice those of euthyroid hormone. Dr. Freedberg and his colleagues therefore postulated a basic difference in the hormone elaborated by thyrotoxic and by euthyroid persons.

Disturbance of Inositol Metabolism in Diabetics.—W. H. DAUGHADAY, J. LARNER, and ELIZABETH HOUGHTON (St. Louis, Mo.) established that in normal people inositol excretion was only slightly influenced by wide variations in inositol intake and urine volume. Diabetics, on the other hand, excreted 5–15 times as much inositol. The amount of inositol excreted was related to the degree of control of the diabetes; higher levels of urinary inositol being found in uncontrolled patients. When the glycosuria was controlled the inositol excretion fell towards normal.

A Pituitary Respiratory-quotient-depressing Factor.—LILLIAN RECANT (St. Louis, Mo.) recalled that hypophysectomised rats have an abnormally high respiratory quotient (R.Q.). The animals' R.Q. can be reduced by giving them anterior pituitary extracts. She found that in Warburg vessels the R.Q. of the normal fasted rat diaphragm was 0·68 in a Ringer-phosphate substrate, but in a glucose substrate it increased to 0·83. In vitro the addition of certain anterior pituitary preparations to the glucose substrate depressed the R.Q. to 0·68. "Growth hormone" seemed most potent in lowering the R.Q. The addition of insulin in vitro did not reverse this effect, but adrenaline and dinitrophenol reversed the action of "growth hormone." To determine the level of intermediary metabolism at which this pituitary R.Q.-depressing factor acted, normal fasted rat diaphragms were incubated with glucose, hexose diphosphate, 3-phosphoglyceric acid, pyruvate, and acetate. Any of these substances caused a rise in R.Q. to 0·83. The addition of growth hormone to the different media inhibited the effects of glucose and hexose diphosphate only. Dr. Recant concluded that the R.Q.-depressing factor inhibits the transformation of hexose diphosphate to pyruvate. Further studies indicated that the pituitary R.Q.-depressing factor is similar to, but not identical with, growth hormone, since R.Q.-depressant activity can be lost without any change in growth activity. On the basis of preliminary observations on serum from fasted patients she suggested that the pituitary R.Q.-depressing factor conserves carbohydrate in the presence of carbohydrate depletion.

Spermine and Tubercle Bacilli.—JAMES I. HIRSH (New York) isolated a crystalline substance from the serum of tuberculous patients which is highly bactericidal to tubercle bacilli in vitro and has been identified as spermine phosphate. In-vitro studies of the action of spermine on tubercle bacilli indicate that it acts only in the presence of minute amounts of a plasma activator, apparently an alpha-globulin, which apparently converts it into an active antituberculous substance.

Viræmia in Poliomyelitis after Infection by a Natural Route.—DOROTHY M. HORSTMANN (New York) infected monkeys either by mouth or subcutaneously with one of two strains of poliomyelitis virus. Virus was recovered from the blood on the 4th, 5th, and 6th days after oral, and the 3rd and 4th days after subcutaneous, infection. Virus was recovered only from the animals which developed paralysis, and these were the only ones that developed antibodies. Viræmia persisted for about 3 days, so it is possible that active viral growth occurred outside the nervous system.

Aromatic Diamidine in the Treatment of Systemic Fungal Diseases.—EMANUEL B. SCHOENBACK and JOSEPH M. MILLER treated various fungal infections with stilbamidine in dosages of 150 mg. daily in three courses, to a total of 4·5–6·0 g. It was ineffectual against histoplasmosis and cryptococcus infections, but highly effective in systemic blastomycosis; the single case of actinomycosis treated responded well to the drug. The only toxic reaction encountered was neuritis, which was common.

Effects of Aureomycin in Undernourished Men.—Stimulated by reports that aureomycin enhances growth in children, GEORGE J. GABUZDA, GEORGE G. JACKSON, and MARGARET E. GRIGSBY studied its effects on 3 undernourished men. The patients were given a diet providing 75 g. of protein and 2800 calories daily, and their body-weights, nitrogen balances, and excretions of riboflavine were recorded. During the preliminary control period, all 3 gained weight and were in positive nitrogen balance. Then they received aureomycin in dosages of 2–3 g. daily for 9 days. None of the patients developed diarrhœa, glossitis, or stomatitis, but soon after the aureomycin was started they began to lose weight, their urinary nitrogen rose, and their nitrogen balance became negative. Their fæcal nitrogen was unaltered. The urinary output of riboflavine increased two or three days before the change to a negative nitrogen balance. When aureomycin therapy was stopped, their weight started to rise once more, their nitrogen balance became positive, and their riboflavine excretion dropped to pretreatment levels. When similar studies were performed with non-absorbable antibiotics (polymyxin and bacitracin) no such effects were observed. The suggested explanation was that aureomycin blocks the utilisation of riboflavine in the cells and thus prevents normal deposition of nitrogen.

Experimental Porphyria in Rabbits.—By feeding 'Sedormid' to rabbits, RUDI SCHMID and SAMUEL SCHWARTZ (Minneapolis, Minn.) produced a condition with the essential features of human porphyria (acute, intermittent, and "mixed" porphyria). The rabbits excrete uroporphyrin and porphobilinogen in their urine in amounts even greater than are found in the human disease. The uroporphyrin is of the Waldenstrom type (methyl ester, m.p. 252°C), yielding on decarboxylation about equal amounts of coproporphyrin I and coproporphyrin III. A further resemblance to the human disease is that the increased urinary coproporphyrin is principally isomer type III, and, like the uroporphyrin, it is excreted as the zinc complex. The bile contains enormous concentrations of coproporphyrin and protoporphyrin and gives an intense red fluorescence. The liver also exhibits this red fluorescence and contains large amounts of uro-, copro-, and proto-porphyrin, as well as porphobilinogen, whereas the amounts of porphyrin found in the bone-marrow and erythrocytes are within normal limits. These findings have obvious implications in human porphyria and porphyrin metabolism in general, for they suggest that the production of porphyrins by the liver is not dependent on the porphyrin formation related to hæmoglobin synthesis in the bone-marrow.

Vitamin B_{12} Levels in Pernicious Anæmia.—Using *Euglena gracilis* for bio-assay, JOHN W. HARRIS (Boston, Mass.) studied B_{12} levels in the serum, erythrocytes, and white cells of 12 normal people and 16 patients with untreated pernicious anæmia. The levels of B_{12} were found to be very low in all three elements of blood from the pernicious anæmia patients, as follows:

	Red cells	*Vitamin B_{12} (µµg.)* *Serum*	*White cells*
Normal persons	36	55	786
P.A. patients	0·5	1·0	131

Treatment with 5 µg. of B_{12} daily raised the patients' levels to about half normal, and 15 µg. daily raised them to about three-quarters of normal. Relapse-rates were found to vary inversely with the amounts of B_{12} given in treatment—the higher the dosage the lower the relapse-rate. On a dosage of 15 µg. daily relapses ceased altogether.

Association of American Physicians

Blood-volume in Congestive Heart-failure.—It is assumed that the blood-volume is *increased* in congestive heart-failure, but JOSEPH J. ROSS, ROBERT B. CHODOS, WILLIAM H. BAKER, and EDWARD D. FRESS have revealed fallacies in this view. They estimated the blood-volumes of patients in failure, and during and after treatment, by the method using P^{32}-tagged red cells. They compared the blood-volumes of 35 patients in failure with 57 normals measured by the same technique, and found no significant difference. When 14 patients in failure were studied before and after successful therapy, they found that 5 had a slight increase and 9 a slight decrease in blood-volume, though the changes were not statistically significant. But when the blood-volumes of patients in failure, calculated by the P^{35}-tagged cell technique, were compared with those of the same patients calculated by the Evans-blue dye technique, the dye method was found to give volumes almost twice those obtained with the tagged cells. After treatment, the dye method revealed a big fall in blood-volume, when the tagged-cell technique indicated no significant change. The reason suggested is that, in failure, the dye diffuses into extravascular fluid, to give an artificially high calculated blood-volume.

Clinical Picture of Hypertension associated with Unilateral Renal Disease.—GEORGE A. PERERA and ARTHUR W. HAELIG compared the clinical features of 20 patients who had been relieved of hypertension by unilateral nephrectomy with 20 patients thought to have hypertension associated with unilateral renal disease who were not improved by therapy. The results can be summarised as follows:

	Relieved	*Not improved*
No. of patients	20	20
Hypertension present over 4 yr. before surgery	1	13
Males	12	7
Diastolic pressure over 130 mm. Hg ..	17	5
Headaches and/or convulsions	15	7
Retinopathy	14	0*
Pyelonephritis as cause of unilateral renal disease	11	5

* Of 10.

Perera and Haelig emphasised that hypertension associated with unilateral renal disease is generally a severe, rapidly accelerating process, often associated with infection in the involved kidney. They suggested that its mechanism is different from those of chronic bilateral renal disease and other types of vascular disease.

Distribution of Nephron Activity in Man.—There are two schools of thought regarding nephron activity: (1) *homogeneity of function*, as outlined by Homer Smith, who believes that all functioning nephrons work at the same level of activity; and (2) *heterogeneity of function*, according to which there are wide differences in function in different nephrons. STANLEY E. BRADLEY, JAMES F. NICKEL, and EDGAR LEIFER studied this problem using tagged urea injected intravenously. They noted a wide difference in specific activity between the serum-urea and the urine-urea in the first hour after the injection, and these activities took a long time to reach equilibrium. This they interpreted as evidence for heterogeneity of function. If all the nephrons functioned at the same rate, it would be expected that shortly after injection, differences in urine and serum urea specific activity would become constant as equilibrium was reached. The delay in reaching equilibrium between urine and serum suggests that some nephrons form urine faster than others—that filtration may be fast in some and slow in others.

Epidemiological Differences Between Acute Nephritis and Acute Rheumatic Fever.—CHARLES H. RAMMELKAMP, jun., ROBERT S. WEAVER, and JOHN H. DINGLE noted a fairly constant relationship between the development of rheumatic fever and the prevalence of Lancefield group-A streptococci, about 3% of all cases infected developing rheumatic fever regardless of the type of group A, the locality, or the clinical form of infection. They found that almost all the cases of acute nephritis followed infection with type 12 of group-A streptococci. Other types less frequently involved were 2, 4, 18, and 31. These strains, particularly type 12, therefore appeared to be specifically nephritigenic. Further studies with type 12 indicated that this organism may attack the kidneys directly at the beginning of infection, in that microscopic hæmaturia was noted about 3 days after infection with this organism, though clinical symptoms developed later.

Distribution of Poliomyelitis in the Epidemic Community.—It is now usually accepted that in epidemics of poliomyelitis a large percentage of susceptible individuals are infected, though few develop the clinical disease. Evidence for this view is the increasing resistance with age, presumably from an active immunity acquired through subclinical infections, suggesting that the infection-rate is high. THOMAS FRANCIS, jun., and his colleagues studied large segments of the community in areas of poliomyelitis epidemics, examining stools from most of the children and many of the adults for polio virus. Their results demonstrated a high incidence of infection in persons in the household of children with clinical poliomyelitis, and a moderate incidence in the close contacts of such children. In the remaining population the incidence of infection was extremely low. Judging from these findings, contrary to the general belief, the infection in polio is concentrated in households where clinical cases occur, and the virus is not uniformly distributed in the community.

Isonicotinic Acid Hydrazide in Tuberculosis.—WALSH MCDERMOTT, CARL MUSCHENHEIM, CHARLES M. CLARK, DUMONT F. ELMENDORF, jun., and WILLIAM N. CAUTHON reported on 80 patients treated at New York Hospital and the Arizona Navajo Reservation. They pointed out first that the maximal activity of the drug in vitro is against active growing bacilli, and that there is no effect against resting organisms; that 0·05 µg./ml. will repress growth in vitro, but 80 times this concentration is needed in the serum. The drug is excreted by the kidneys, and diffuses throughout the body-fluids and to a lesser extent into the cerebrospinal fluid. It is active at the low pH range of inflammatory tissue, unlike streptomycin, and is effective against intracellular as well as extracellular forms of the organism. In the patients studied, the usual dosage was 5 mg./kg./day, given in 3 or 4 divided doses. In meningeal or miliary tuberculosis larger doses, up to 10 mg./kg./day, were used for the first week. *No* toxicity was noted at these dosages. The best results were in patients with miliary and/or meningeal tuberculosis where the course and outcome are known and predictable. Of the 9 miliary cases studied, 4 of which had meningitis, 2 began treatment too recently to be reported on; 2 have died, and 5 have recovered. Improvement was observed within 7 days of the start of therapy. X-ray clearing was seen in 2–4 weeks, and defervescence of clinical disease in from 7 days to several weeks. There was definite evidence that the drug possessed a high degree of antituberculous activity. Of 8 cases with meningitis alone, 2 died within the first week of treatment; the other 6 improved, though not so dramatically as the miliary cases. Though 38 pulmonary cases have been studied, only 9 have been observed for 3 months or longer. Most have shown general improvement with improved appetite, gain in weight, fall in temperature, and lessening of cough. No patient has suffered an increase in his disease while under treatment. However, while the evidence supports the view that the drug is highly active in pulmonary tuberculosis (as in miliary and meningeal), the observations have been too short for definite conclusions to be drawn. As to bacterial resistance, this is a much more complicated problem than with streptomycin, since one can find strains resistant to this drug in any patient, whether or not he has been treated with it. The indications are that for the tubercle bacilli to develop a significant degree of resistance will take at least as long as with streptomycin.

Excretion (and Absorption) of Co^{60}-labelled Vitamin B_{12} in Pernicious Anæmia.—After giving vitamin B_{12} labelled with radioactive cobalt, by mouth ROBERT W. HEINLE, ARNOLD D. WELCH, VICTOR SCHARF, GORDON C. MEACHAM, and WILLIAM H. PRUSOFF studied stool excretion of the vitamin in normal subjects and P.A. patients. The normal people were found to absorb most of a small dose (0·5 g.). With larger doses there was less absorption. Adding intrinsic factor (derived from human gastric juice or hog-stomach extract) did not increase absorption. Four P.A. patients, however, were found to excrete 72–96% of orally administered radioactive B_{12} in their stools. When small amounts of intrinsic factor (3–10 mg.) were added, then stool excretion dropped to 25–30%. Larger amounts of intrinsic factor did not lead to any further absorption, though when less intrinsic factor was added absorption decreased. This poor absorption of B_{12} and the improvement with additional intrinsic factor might prove a useful tool in the diagnosis of pernicious anæmia, particularly in patients who have been treated before a reliable diagnosis has been made.

CHIEF CHARACTERISTICS OF NERVE GAS

WITH NOTES ON FIRST-AID TREATMENT *

"Nerve gases" are liquids with boiling-points varying from 150° to 250°C (approx.). They are therefore roughly comparable in volatility to kerosene. They are fairly soluble in water and are slowly destroyed by hydrolysis. Alkalis such as solutions of caustic soda or washing-soda will decompose them more quickly. They are almost odourless and the vapour is invisible. They have no immediate irritant properties either to the eyes, skin, or respiratory tract. No warning of their presence is therefore given to the subject exposed to them.

MODE OF ACTION

Their very dangerous and insidious qualities are primarily due to the fact that their action is that of cholinesterase inhibition—i.e., they prevent the action of the enzyme which, under normal conditions, continuously destroys acetylcholine in the body as it is produced. This leads to the accumulation of acetylcholine and hence all neuromuscular mechanisms are upset. Voluntary muscle, including the muscles of respiration, ultimately becomes paralysed and smooth muscle passes into a state of spasm. In effect there is a generalised parasympathetic stimulant action.

The total amount of cholinesterase in the body is small and nerve gases inhibit this enzyme for a prolonged period. Therefore, these gases are highly toxic and may be lethal in minute concentrations. They are rapidly absorbed either by inhalation of the vapour, absorption of the liquid through the skin and mucous membrane, or by the ingestion of contaminated food or water. A drop of liquid in the eye or the inhalation of a high concentration of vapour for a few seconds may cause incapacity or death within a few minutes. Liquid on the bare skin penetrates somewhat less rapidly, but two or three drops may kill within half an hour. Ordinary clothing cannot be relied on for protection as it is quickly penetrated.

The inhibition of cholinesterase activity may persist for many weeks so that repeated exposures to very low concentrations may have a cumulative effect.

SIGNS AND SYMPTOMS OF POISONING

These can be divided into primary and secondary.

Primary due to direct action of the nerve gas.—There is copious salivation, slowing of the heart, constriction of the pupils, headache, nausea, diarrhœa, vomiting, muscular weakness, and sometimes generalised muscular fibrillation. The muscles of respiration are weakened or paralysed, the diaphragm being affected most. The bronchial musculature may be in spasm.

Secondary due to the anoxia brought about by respiratory paralysis.—This will produce cyanosis, venous congestion, low blood-pressure, convulsions, and possibly pulmonary œdema.

Death occurs suddenly from the effects of the anoxia.

CLINICAL FEATURES

Since comparatively few cases of poisoning have occurred, the clinical picture is as yet imperfectly known. The following summarises the features which have been recognised.

A severe case of nerve-gas poisoning will present itself as one of acute asphyxia. The subject may be unconscious from anoxia with cyanosis, sweating, and pallor. Breathing will be laboured and wheezing in character, similar to that of an acute asthmatic attack. While conscious, the subject will be anxious and suffering from air-hunger, there may be restlessness and lack of coöperation due to the effects of the anoxia.

In mild cases the main respiratory symptom will be tightness of the chest and throat. There will be intense headache, constriction of the pupils, and difficulty of near vision. There may be nausea, vomiting, dizziness, abdominal pain, and diarrhœa. These symptoms may commence several hours after exposure and may persist for days if untreated.

POST MORTEM

No specific changes other than those due to anoxia are found. The accumulation of acetylcholine causes death by an interference with function and not by destruction of tissue. There is cyanosis of the viscera and blood and congestion of the brain and conjunctivæ. There may be a dilation of the heart. The speed of post-mortem autolysis will be increased.

TREATMENT

To be of use this must be immediate, because of the danger from anoxia. Atropine is the antidote to the nerve gases. If there is severe respiratory distress and cyanosis, artificial respiration must be started at once and maintained until adequate respiration returns of its own accord.

Antidote.—Subjects suffering from nerve-gas poisoning tolerate large doses of atropine. An initial dose of 2 mg. (gr. $^{1}/_{32}$) should be given intramuscularly. This dose should then be repeated—by either the intravenous or intramuscular route—until such time as the symptoms of poisoning disappear. A useful sign of the degree of atropinisation achieved is the pulse-rate, and the dose of atropine should be repeated so as to maintain a pulse-rate of 110–120 beats/minute. (The

Fig. 1.

---

* A memorandum from the Ministry of Supply.

signs of atropine poisoning are largely psychotic, with mania, extreme excitement, and restlessness. The latter must not be confused with the restlessness that occurs following anoxia. As much as 12 mg. atropine sulphate in 16 hours has been given in nerve gas intoxication.)

Artificial respiration.—The method recommended is a small hand bellows which will ventilate the lungs in spite of the bronchial constriction. When using the hand bellows the patient should be supine and the attendant should kneel to the right of the head. His left hand should encircle the face and hold the face-piece firmly in position (fig. 1); the face-piece must fit under the chin. The attendant's other hand should work the bellows so that the main force is exerted at an angle of 30° to the horizontal (fig. 2). This is to ensure that the lower jaw and tongue do not fall back and obstruct the air-passages. The pressure used should not exceed 20 cm. of water, since with higher pressures the lung and stomach may be overinflated. The resuscitator illustrated has a safety valve on the face-piece which blows off at 20 cm. Ventilation should be carried out at a rate of 20 to 30 times a minute and should be continued until the subject is capable of breathing adequately himself. This will probably occur within 30 minutes, but it must be remembered that respiration may fail again due to excessive elimination of carbon dioxide during the artificial ventilatory period; hence the subject should be kept under observation. During artificial ventilation the stomach will be inflated with air by the resuscitator. This will cause some respiratory embarrassment when normal respiration is re-established. It can be minimised, however, by firm pressure over the stomach, applied intermittently to force the air up the œsophagus. During this manœuvre the patient's head and shoulders should be raised, so as to ensure that it is air and not the liquid contents of the stomach which is forced into the œsophagus. While artificial ventilation is being carried out, there will be excessive salivation and, if practicable, this should be allowed to drain away by periodically tilting the subject's head down. If no form of positive pressure ventilatory apparatus is available then manual artificial respiration should be performed. Oxygen, if available, should be used in conjunction with this.

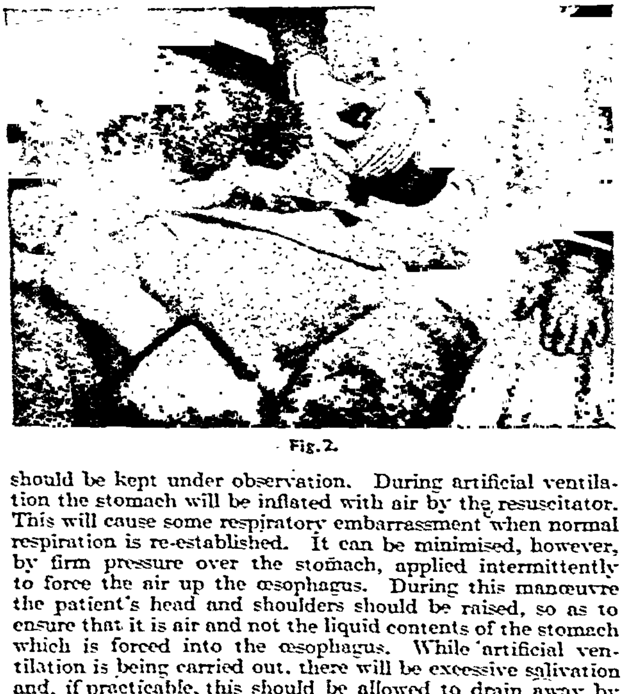

Fig. 2.

In mild cases of nerve-gas poisoning the eye symptom and headache are best treated by the instillation of atropine drops or ointment in the eye. This should be used as an adjunct to parenteral atropine therapy if necessary.

DECONTAMINATION

In the event of toxic liquid being splashed on the skin it should be washed off immediately with plenty of water. As soon as this has been done, ordinary anti-gas ointment should be applied as the subject will be unable, at this stage, to know whether the liquid is nerve or mustard gas.

If the clothing is contaminated, the outer clothing should be removed at once and the skin washed as soon as possible.

The above first-aid treatment should be within the competence of trained non-medical personnel and, in certain emergencies, will have to be carried out by them to save life.

In England Now

A Running Commentary by Peripatetic Correspondents

THE subject is wastage in beddage—horticultural, domiciliary, and institutional.

Crawling over a neglected flower-bed, I began to wonder why we laboriously collect the decayed greenery, transfer it to the compost-heap, turn it, secundem more or less artem, into compost—which would be done by Nature and Time if it were left in situ—only to transfer the result back to the original beds in due course. No doubt a neglected bed is a better medium for insects and other pests; but mere tidiness, the gardener's Old Man of the Sea, plays a big part. A welcome transition brought me to my Morphean couch; and here again I spent time and effort removing the bedspread, the eiderdown, and most of the blankets, which are unnecessary in summer but which feminine tidiness replaces—without, usually, the excuse of pest harbourage—every morning in a hundred thousand homes.

Next day, brooding over some statistics which seemed to show extraordinary variations between the turnover per bed in comparable hospitals and departments, I began to wonder whether the same factor might not be at work. How Sister's heart must rejoice at the incomparable tidiness of a well-made empty bed compared to the amorphous and unattractive spectacle of a bed with a patient in it! To those immediately concerned, a high turnover brings more work—and nothing much else. Yet if an empty bed always called for an explanation our waitage might show shrinkage.

* * *

Pending the arrival of atomic energy as the everyday means of supplying most of our material needs we ought, I feel, to be making more widespread use of interim measures. Think, for example, of all the energy expended and at present running to waste in the whole field of sport. If we could but harness all the work done in all the football matches throughout the season we should be well on the way to providing ourselves with all the electricity we need. And think of the ergs that go down the drain, so to speak, in any given cricket season, Grand National, Henley, or Wimbledon—to say nothing of Olympic Games. Nor should we neglect those unnamed heroes and heroines who bicycle madly about the country at weekends, nor those who pad around on dance floors for hours on end.

To chaps who understand these things erg-collecting on this grand scale should present but a trifling problem in applied science.

* * *

Others have remarked—perhaps even in these columns—that the world seems to shrink every year, and at an increasing rate. No sooner has one adjusted one's ideas to rounding the world in 80 days than somebody does it in a week, 3 days, 2 days, and so on. It didn't seem natural to me that I could spend 13 days on holiday in Newfoundland and be back again before Billy Bloggs was free of infection from the chickenpox I diagnosed on the day I set out. But so it was.

Prestwick to Gander was a 10½ hours' trip, and the tilt-back chairs, with barley-sugar and blankets thrown in, made the journey less trying than a long railway journey. Gander was dark, cold, and uninteresting; but Newfoundland itself, with its forests, lakes, and rivers, is a grand place for holidays of the heartier kind. Unexpectedly the mosquitoes did not bite—presumably they could find better fare than a British-fed G.P. We swam, we boated, we sunbathed, and we ate. We drove the 180-odd miles to Corner Brook to attend some medical lectures and inspect the newly opened hospital and sanatorium, which incidentally compare favourably with their opposite numbers in Britain. We went to Grand Falls and explored the paper mill. We visited Botwood and its hospital, and took a boat down the river. At Bishops Falls I swam in the Exploit, ate a week's ration of meat at a sitting, saw the local robins which are as big as our thrushes, and was chased by a bittern. I sat through a baseball match, sampled hamburgers and "spare ribs," and listened to "Laura," the Newfoundland equivalent of Mrs. Dale, on the radio. For 13 days I forgot all about telephone calls and night bells.

Back at Gander I was told that my B.O.A.C. plane was held up with "mechanical trouble" in New York; but the ever-helpful airport officials found me a seat on a Pan-American plane, and in 12 hours I was in London, after a holiday that was "completely different" and one of the best ever.

* * *

Complaints of over-specialisation in the profession and fears for the status—or the continued survival—of the G.P. are no new thing. In 1500 B.C. the citizens of Thebes were lamenting the lack of good family physicians of the old school, for Herodotus later reported: "The practice of medicine is so divided among them that each physician is a healer of one disease and no more. All the country is full of physicians, some of the eye, some of the teeth, some of what pertains to the belly."

It seems strange that the ancient Greeks did not have a word for each and every specialty, but perhaps they had more respect for their language, from which we moderns fashion such monstrous hybridisms.

* * *

A letter we have had from our regional hospital board begins with this sentence:

> "Under a suggestion made by the Department of Health for Scotland, the *Regional Hospital Board has been considering* the possibility of the establishment of some periodically-functioning machinery through the agency of which the effects of changing circumstances upon the individual time-factor of medical staff contracts may be ascertained."

It left most of us "like one that hath been stunned and is of sense forlorn."

* * *

I have never been able to understand the intricacies of sight-testing, with its cylinders and sphericals and axes and dioptres, and when I visited an optician lately for a check-up on my friendly but failing glasses, I was greatly impressed by the latest contraptions for accurate measurement. I was duly impressed, too, when, after a succession of flicks and clicks, I was able to read the smallest letters at the prescribed distance and see transverse and horizontal lines in the uniform black of corrected astigmatism. In a week or two I got my new glasses, splendid things that gave me a fine feeling of dignity and importance.

A few days later when I was shaving, and more than usually interested in my face, I noticed that the hinges of my new spectacles were not bilaterally in alignment with my external canthi—one hinge being above and one below. Greatly worried lest I might be wearing out my eyes by making them look through cockeyed lenses I called on the optician. He was gracious; he smiled at my complaint; he asked me to look at the bridge of his nose. I noticed that his glasses were very neat. I felt confident. "You see," he said, "your glasses appear to be just a fraction of a millimeter out of the level when judged by the corners of your eyes; but that's your fault—your eyes aren't exactly level, nor, for that matter, your ears." "So that's it, is it?" I said. I know that one of my shoulders droops, because I've been told repeatedly by my various tailors; but I have my full share of vanity when my face is the subject of conversation. So I did not follow up the pros and cons of my asymmetry. After all, I thought, I might easily be told I wasn't level-headed.

* * *

There has been a good deal of discussion lately about the free use made of human volunteers in experimental work. Some of them seem to be very willing and very tough, judging by a description in the *Proc. Soc. exp. Biol. Med.* (1952, 79, 296) of the treatment given to a pharmaceutical graduate. Some of the details of his, or her, experiences are unfortunately left to the imagination, but, "the filter candle" we read "was placed in a pharmaceutical graduate with a narrow bottom . . . the filterable material was then removed through the filter by suction. . . ." Then there is a reference to "the non-filterable residue on . . . the bottom of the graduate." We are also told that "all these procedures were carried out at about 0°C." I think I should have found the technique easier to follow if the article had been illustrated.

Letters to the Editor

MALARIA IN EX-SERVICEMEN

SIR,—The letters from Professor Macdonald and from Dr. Adams and Dr. Seaton in your issue of July 5 emphasise once more the importance of thinking of malaria when a Serviceman, or ex-Serviceman, presents with an unexplained fever.

Since February, 1952, no fewer than 52 cases of malaria have been treated in the Military Hospital, Tidworth. 31 of these patients have served in Korea, 15 in Malaya, and 6 in Hong-Kong. Without exception the patients had been on a suppressive dose of 100 mg. of proguanil ('Paludrine') daily while overseas; the drug was stopped either on embarking at the overseas port, during the voyage home, or just before disembarking in this country. Most of the cases were experiencing their first attack and it is noteworthy that, in the majority, symptoms did not begin until six months after stopping suppressive proguanil.

In all the cases the parasite was *Plasmodium vivax*, which causes the "benign tertian" fever. Some showed the typical high fever preceded by a rigor and followed by an afebrile phase; others complained merely of vague generalised body pains and headaches, and these were often accompanied by a low irregular fever. On the whole the illness has not been severe and in many of the cases the spleen was not palpable. Recovery, on specific treatment, has been rapid and so far only 1 case has had a relapse.

Military Hospital, Delhi Barracks,
Tidworth, Hants.

R. G. MACFARLANE.

*** It will be useful to many readers to have particulars of the methods of malaria treatment now used in the Army, and we are glad to be able to publish here some extracts from notes put at our disposal by the Director-General of Army Medical Services.—ED. L.

From time to time general practitioners in this country are called upon to treat malarial attacks in ex-Service personnel who have recently returned from overseas, or in Service personnel on leave. Relapses of benign tertian infections are most frequently met with; but it should be remembered that the initial clinical attack may occur in the United Kingdom although the actual infection took place months previously. Less commonly, malignant malaria may occur for the first time in a patient recently returned from the tropics.

Delay in diagnosis may have disastrous consequences, especially in virulent or heavy falciparum infections, when cerebral symptoms or collapse may occur with dramatic suddenness. The key to the diagnosis is the finding of malarial parasites in the blood, and in all suspected cases blood films should be taken at once and steps should be taken to have these examined without delay.

In the treatment of benign tertian malaria, quinine and pamaquin, or 'Chloroquine' ('Nivaquine' is the British equivalent) and pamaquin, should be used. The following course is the most likely to cure the condition and lessen the chance of relapse:

> Quinine bihydrochloride gr. 10 t.d.s. for 14 days in conjunction with pamaquin 0·01 g. t.d.s. for 14 days.

If the patient has had a previous attack the length of the quinine-pamaquin course may be extended to 21 days.

As an alternative chloroquine (nivaquine) may be given as follows:

1st day: 0·9 g. base (6 tablets).
2nd day: 0·6 g. base (4 tablets).
3rd to 5th day: 0·3 g. base (2 tablets). Total: 16 tablets

with pamaquin in the same dosage as before. During this treatment the patient should not be allowed to go about and is best treated in bed.

Malignant tertian malaria without pernicious manifestations can be treated with the course of chloroquine given above. Pamaquin is not required, for there is little tendency to relapse. However, it is best to have such cases admitted to hospital, because severe or pernicious symptoms necessitate the immediate administration of intravenous quinine. Mepacrine is still used in the routine treatment of uncomplicated malignant tertian malaria and as an alternative to quinine or chloroquine. The recommended course is:

1st day: 0·3 g. (3 tablets) t.d.s.
2nd and 3rd days: 0·2 g. (2 tablets) t.d.s.
4th to 7th day: 0·1 g. (1 tablet) t.d.s.

Proguanil ('Paludrine') is not used in the treatment of malaria in the Army, although it is extensively used for suppression and has almost completely replaced mepacrine for this purpose.

SKIN BANKS

SIR,—The institution of "skin banks"—i.e., stores of human skin that might be drawn on for certain acute surgical emergencies—is known to be technically feasible.[1] On the other hand, it is almost universally agreed that skin homografts can never be used for permanent repair, so that apparently such banks could at best be of only very minor value. My purpose here is to show that the expectation that skin homografts will always fail is needlessly pessimistic.

It is not known with certainty how many distinct antigenic factors there are which, present in the homograft but absent from the recipient, will cause a homograft to break down. From what is known of skin grafting in rabbits[2] and the transplantation of tumours in mice,[3] it may be said that 20 is a fair guess, in which case the number of possible antigenic compositions is over a million.

If A and B are two individuals selected at random from the population, then the probability that B's skin would form a permanent graft upon A may be as high as 1/300. Thus a bank containing the skin of a few thousand individuals may have a high probability of containing skin acceptable by a random individual in need of a graft. (The bank would differ from a blood bank in that there would be no certainty.) The bank could, of course, consist merely of a card index, provided that the donors themselves were readily accessible. All this depends on the ultimate possibility of being able to analyse antigenic composition, and researches which may lead to successful antigenic analysis are thus of more than academic interest. An individual who had volunteered as a donor would have the advantage that if he became a casualty his composition would be known without delay.

Among the thousands of skin-homografting operations that have been tried in a speculative spirit by surgeons, just a few between unrelated individuals may well have succeeded. In 1943 Medawar[4] said: "It is certainly possible that isolated genuine claims for the persistence of homografts have been overridden by our now almost comprehensive scepticism," but he informs me that he did not really think it was at all likely. Any alleged claims of success should be supported by the fullest documentary evidence, since the prior chance of success on any given random occasion is small, even if larger than has often been supposed.

A curious fact is that a knowledge that B's skin is tolerated by A decreases the chance that A's skin is tolerated by B, assuming that A and B are not relations. (This result can be completely proved if no set of antigens are determined by multiple allelic genes other than diallelic ones.) It follows that when testing two individuals for being identical twins rather than being unrelated it is important that grafting should be done in both directions, as in a recent example.[5]

A skin antigen has (by definition) the property that if it is present in B but not in A, then B's skin is not acceptable by A. The condition for the acceptance of B's skin by A is, then, that A should "antigenically include" B—i.e., that A should have every skin antigen that B has.

Let the possible human skin antigens be $a_1, a_2, \ldots, a_n$ and assume for the present that no group of these is determined by allelic genes. Let the probability that an individual has antigen a_i be p_i and write $\pi_i = 2p_i - 1$. The probability that A does not have a_i while B does is $(1-p_i)p_i = (1-\pi_i^2)/4$. The probability that a_i is harmless when B is the donor is therefore $1-(1-p_i)p_i = (3+\pi_i^2)/4$. Assuming independence, the probability that A "antigenically includes" B is

$$p = \prod_{i=1}^{n} \frac{3+\pi_i^2}{4} \cdot \qquad (1)$$

If there is linkage the probability will be even higher. Now it may be optimistic to take $n = 20$ but it would be pessimistic to take all the π_i's equal to zero. So it may not be far from the truth to say that

$$p \simeq \left(\tfrac{3}{4}\right)^{20} \simeq \frac{1}{300} \qquad (2)$$

The probability that A's antigens include B's and vice versa—i.e., that A and B are antigenically the same—is

$$q = \prod_{i=1}^{n} \{p_i^2 + (1-p_i)^2\} = \prod_{i=1}^{n} \frac{1+\pi_i^2}{2} \cdot \qquad (3)$$

It is easily seen that $p^2 > q$ since

$$\left(\frac{3+x^2}{4}\right)^2 \geqslant \frac{1+x^2}{2},$$

equality occurring only if $x = \pm 1$. The inequality $p^2 > q$ implies the "curious fact," mentioned above, for the case where no two antigens are determined by allelic genes.

A slight modification is required corresponding to diallelic pairs, a_i, b_i (analogous to the blood factors M, N in man). The probabilities of the compositions a_ia_i, a_ib_i, and b_ib_i are p_i^2, $2p_iq_i$, and q_i^2 where $q_i = 1 - p_i = \frac{1}{2}(1-\pi_i)$. The factor $(3+\pi_i^2)/4$ in (1) should then be replaced by $p_i^4 + 2p_iq_i + q_i^4 = (5 + 2\pi_i^2 + \pi_i)/8$. This is slightly greater than $\left(\frac{3+\pi_i^2)}{4}\right)^2$ so we are slightly better off when two antigens are found to correspond to diallelic genes. (This result does not generalise to the triallelic case.) For example, if $n = 20$ and if the antigens correspond to ten pairs of diallelic genes and if all $\pi_i = 0$, then p is $(5/8)^{10} \simeq 0{\cdot}01$.

The probability that A and B are antigenically the same with respect to a diallelic pair is $p_i^4 + 4p_i^2q_i^2 + q_i^4 = (3 + 2\pi_i^2 + 3\pi_i^4)/8$. The "curious fact" is now implied by the inequality

$$\left(\frac{5+2\pi_i^2+\pi_i^4}{8}\right)^2 \geqslant \frac{3+2\pi_i^2+3\pi_i^4}{8}.$$

This fact also does not apply to the triallelic case in complete generality.

I am much indebted to Prof. P. B. Medawar, F.R.S., for encouragement and useful suggestions.

London, N.W.2. I. J. GOOD.

MILIARY TUBERCULOSIS DURING CORTISONE THERAPY

SIR,—I have recently seen a similar occurrence to that described by Dr. Harris-Jones and Dr. Pein in their article of July 19 (p. 115).

My patient, a woman of 25, was first seen in May, 1950, with typical subacute systemic lupus erythematosus; she had a characteristic rash, arthritis, and fever with the usual biochemical and hæmatological findings. With one or two remissions she survived until March, 1951, when she was admitted to hospital in an acute phase; at this time Hargraves's cells were numerous, the direct Coombs's test was positive, and cold agglutinins were present in the blood to a titre of 1/128 at 18°C (there was even some agglutination at 37°C). The initial response to cortisone in doses of 200 mg. a day was dramatic. However, this was not maintained and the symptoms started to "escape" after two weeks of treatment. At the end of a month she had received 3500 mg. of cortisone, and it is interesting to note that during this period the striking hyperglobulinæmia (albumin 2·0 g., globulin 5·4 g. per 100 ml.) never varied. By the time cortisone had been stopped she had developed deafness, and other symptoms of tuberculous meningitis soon became apparent; this was confirmed by lumbar puncture, and she died a meningitic death. At necropsy the meningeal changes were typical, and the focus from which tuberculosis had disseminated was a soft but partly calcified paratracheal gland; there was no active lesion in the lungs. A further interesting observation was that during cortisone treatment she developed a whitlow which had failed to heal after five weeks. It was felt that this delayed healing was comparable to the breakdown of a previously well-scarred tuberculous focus.

I feel that the lighting up or reactivation of a latent tuberculous focus during the administration of cortisone is directly comparable to the behaviour of the whitlow in my patient. I have little doubt that tuberculosis is sometimes an important factor in the pathogenesis of both discoid and systemic lupus erythematosus, but it is not invariably so, and the evidence produced by these two patients does not specifically incriminate tuberculosis as the cause. Streptococcal infections are as frequently culpable, as are many other infective processes, drug reactions, and more obscure phenomena. Lupus erythematosus should not be classified (as it is in many textbooks) with tuberculous diseases of the skin, but rather with erythema induratum and erythema nodosum, which are morphological reactions stimulated by many processes, of which tuberculosis is only one.

St. George's Hospital,
London, S.W.1.

STEPHEN GOLD.

HOSPITAL HYGIENE

SIR,—Recently I returned as a patient to my old teaching hospital, one of the largest in the country. Whilst my treatment was exceptionally good in every way, I was astonished at the primitive method of washing crockery on the wards.

I wonder how many hospitals have heard of the researches of Dr. Betty Hobbs and her colleagues on this matter, and whether any hospital practises the two-sink method. So long as hospitals are backward in this respect it is difficult for the medical profession to exert strong pressure on the café proprietor. Possibly some useful work might be done by hospital bacteriological laboratories.

M.O.H.

EXTENDING BATTLE'S INCISION

SIR,—Battle's incision has many advocates and detractors, each group with strong feelings on one or more of the drawbacks or advantages of its use. While preferring the crease incision wherever possible, and the paramedian if there is any real doubt as to diagnosis, I have often used Battle's incision. From time to time when using this incision I have, on opening the peritoneum, found conditions (e.g., intestinal, ovarian, or uterine) which could not be handled within the safe limits of extension of this incision. On these occasions I have found the following manœuvre simple and effective.

The small opening in the peritoneum is usually made vertically, behind the nerves, if necessary, and, on deciding that much more room is required, the wound is allowed to fall back into its natural layers. The skin incision, just external to the middle of rectus muscle is freely extended in this line. The incision in the anterior sheath is now also extended, but passes more medially as it goes till it is on the medial side of the middle line of the rectus. The muscle, with its vessels and nerves is now displaced laterally, till we meet our original incision in the peritoneum, and this can be enlarged as much as required—as in the paramedian incision which, indeed, it now is.

I have not seen or heard of this method in use, and feel it may be of interest to others faced with a similar problem.

Senior Surgical Registrar,
Wolverhampton Group of Hospitals.

HENRY B. YOUNG.

SUCCINYLCHOLINE

SIR,—I was interested to read the letter by Dr. Kay (July 26) on the use of succinylcholine in 30 appendicectomies. I have been using this drug recently, usually in conjunction with the thiopentone–nitrous oxide/oxygen–pethidine sequence, to produce muscle relaxation in various operations. My findings agree with those of Dr. Kay. The cases have included appendicectomies, herniorrhaphies, repairs of perforated peptic ulcer, [illegible], several laparotomies, and two subtotal [illegible] appendicectomy and herniorrhaphy a total dosage of 100–150 mg. in divided doses is usually ample.

Succinylcholine has been especially helpful to the surgeon in herniorrhaphies, for it allows relaxation and normal muscle tone to be produced at will, so enabling the surgeon to determine exactly how much to close the internal ring, and how tight to make the 'Nylon' repair.

Dr. Kay writes: "Whether it is possible to retain spontaneous respiration still seems uncertain." In my limited experience it has been possible with a continuous drip to maintain spontaneous respirations of reduced amplitude and yet obtain "spinal-like" relaxation. However, the dose which produces relaxation is so close to that which causes paralytic apnœa that spontaneous respiration may be difficult to maintain with intermittent doses.

A drawback to the use of succinylcholine in major abdominal surgery would appear to be a tendency to increased bleeding associated with a moderate hypertensive effect. I have observed this on several occasions even though the total dosage of the drug was minimal —e.g., 450 mg. over 2 hours and 800 mg. over $2^1/_4$ hours for two subtotal gastrectomies. Possibly some degree of carbon dioxide retention was responsible.

London, N.16.

E. HARVEY FRANKS.

SIR,—I agree with Dr. Foldes (Aug. 2) that a dose of succinylcholine chloride that is less than 1·1 mg. per kg. is sufficient for intubation. In our paper we stated (p. 1226): "These doses (1·1 mg. per kg.) are safe, but smaller ones were often found satisfactory." I believe that the optimum dose lies between 0·55 and 1·1 mg. per kg. In a few patients receiving 0·55 mg. per kg. relaxation was only just adequate.

In my experience with 740 patients, using doses within this range, I have occasionally found slight delay in recovery, but in no patient did apnœa exceed 15 minutes.

Dr. Foldes regards apnœa as an undesirable side-effect of using a muscle relaxant. When using a short-acting relaxant, such as succinylcholine, I do not agree with this. A patient fully paralysed and artificially ventilated provides better operating conditions than one in whom both respiration and relaxation may be inadequate. This difference from Dr. Foldes in viewpoint accounts for why I prefer a higher dose by intravenous infusion for abdominal relaxation.

I agree with Dr. Green (Aug. 2) that I have used by infusion doses which are greater than necessary for complete relaxation, and that with smaller doses delay in recovery is less likely. Nevertheless, contrary to his statement, the doses I gave fell within the range (2 to 15 mg. per minute) which Dr. Green found effective.

Before using succinylcholine for abdominal relaxation it is advisable to test the patient's ability to recover from a standard dose. This test may conveniently be made at the time of intubation by giving a dose that is 1·1 mg. per kg. immediately following thiopentone. The duration of the ensuing paralysis is a guide to subsequent dosage, whether by intermittent injections or by continuous infusion.

London, S.E.1.

J. G. BOURNE.

SORE THROAT AND RHEUMATIC FEVER

SIR,—The letter from Dr. Alice Stewart and Mr. David Hewitt (July 19) reveals what seems to me a tortuous method of reasoning. The value of tonsillectomy in preventing acute rheumatism is assessed on an analysis of a tiny number (70) of children who had suffered from tonsillitis but not developed rheumatism, and a minute number (31) of rheumatic children who have previously suffered from tonsillitis. I am irresistibly reminded of the pottery manufacturer who discovered that not one of 100 users of his pottery had suffered from acute appendicitis, whereas every one of 100 cases of appendicitis had used glass-ware in one form or another. The inference was obvious.

Surely the only sound way to assess the value of tonsillectomy in preventing rheumatic fever is to follow up the history of a few thousand children who have had their tonsils removed for tonsillitis, and a few thousand children who have not had their tonsils removed in spite of tonsillitis, and to find out what proportion of the two groups subsequently developed rheumatic fever. This was done over 20 years ago by Kaiser.[1]

Truro, Cornwall. County Medical Officer.

INTRA-ARTERIAL TRANSFUSION

SIR,—Prof. D. L. C. Bingham (July 26, p. 157) appears to be unaware of all the experimental and clinical work which has been done in the Soviet Union on resuscitation by intra-arterial centripetal blood-transfusion after the publication of Birillo's article in *Khirurgiya* of 1939. One of the chief aims of such transfusion has been to raise the pressure in the ascending aorta sufficiently to re-establish the circulation in the coronary arteries: the blood-pressure is then maintained, in successful cases, by the force of the resumed cardiac contractions.

London, S.W.16. L. CROME.

SIR,—Professor Bingham has done a service in emphasising the value of intra-arterial transfusion. His conclusion, based on a relatively large number of cases, that this route is far superior to the intravenous one in the prevention and treatment of oligæmic shock, agrees with the clinical and experimental findings of others and indicates the need for all to be familiar with the intra-arterial route if the maximum of lives is to be saved.

Unfortunately, the use of peripheral arteries in this procedure is somewhat hazardous, and Professor Bingham adds one more case of peripheral gangrene to those already reported. In addition, there may be difficulty in entering the lumen of a peripheral artery contracted in severe shock, and vasoconstriction can interfere markedly with the transfusion in the very cases where it is most needed.[2]

These difficulties and dangers are obviated by the intra-aortic route which I have practised for twelve months, with a report on the first 10 cases.[3] The needle used is a stepped one, rather like a Finsterer splanchnic needle, with a stem 16 cm. long by 3 mm. diameter and a terminal section 0·75 cm. long and 1·5 mm. diameter. This is inserted in the left lumbar region much as for paravertebral injection of the sympathetic chain but rather further from the midline. The point can be quickly and easily inserted into the aorta and blood introduced rapidly under pressure. I use a simple apparatus similar to that of Professor Bingham but with a two-way tap at the site of his Y-tube. This allows direct readings of the aortic blood-pressure to be made, and these are interesting and helpful in assessing the response to the transfusion. Cases varying in age from two days to eighty-four years have received transfusions by this route, and my impression is that improvement in the general condition is much more rapid than with intravenous transfusion of similar amounts. For example, 3 patients exsanguinated by repeated gastric hæmorrhages were restored to good general condition with 1½–2 pints of blood in twenty minutes, and came through immediate partial gastrectomy without any trouble.

The aorta is relatively constant in position, contains little muscle tissue and so cannot go into spasm, and is sufficiently wide to preclude any chance of obstructive thrombosis developing. Puncture with a reasonably fine needle is free from complications; large series of punctures for aortography have been reported without mishap, and in those patients of mine who died because of the primary disease post-mortem examination revealed little or no trace of the procedure.

In addition to its suitability for preoperative transfusion, the aorta is accessible in both abdominal and thoracic operations, and direct transfusion with a shorter needle could be easily and quickly carried out. It is now my practice to have a suitable apparatus at hand during the performance of such operations as those for Fallot's tetralogy and aortic coarctation lest the need for rapid transfusion should arise.

Crumpsall Hospital,
Manchester. H. A. HAXTON.

MORE MANURE

SIR,—Your annotation of April 12 refers to an address given to the Royal Society of Arts by Mr. J. C. Wylie, of Dumfries. I should like to add a contribution to what Mr. Wylie said on sewage wastes. With the idea of saving money every farmer seeks to dismiss labour. He regards labour as the greatest item of cost in production. He buys a machine and dismisses a man, with the result, from the nation's standpoint, that labour is transferred from the land to the factories. The consequence of this craze for the dismissal of labour (which is leaving our land in thousands a year) is that every operation has to be mechanised and simplified. The spreading of bulky farmyard muck becomes less possible, and the substituted spreading of artificial fertilisers is so easy. The fact that it costs a lot of money to buy artificials does not seem to weigh with farming intelligence. The husbandman is so determined to reduce wages that he dismisses a man and buys more machines and more artificials. This is leading the country into a serious state of affairs, because diseases of all kinds are beginning to show themselves in both crops and livestock, and they are not yielding to remedial treatment.

With the spread of disease, the problems of the farm are mutiplying; but the farmer continues to dismiss his men and buy more machines. This brings me to the problem underlying Mr. Wylie's recommendation—namely, that of composting sewage wastes and making use of these as fertilisers on the land. These sewage wastes, mixed with farmyard manure and an adequate amount of waste vegetation (the latter is an elementary essential) would make a re-fertilising agent of immense value, but the labour is not available. Although machinery, such as the Rapier Muck-shifter, has been invented to make mechanical compost, these machines are expensive to buy, and they have not met with response in farming circles, because the farmer is now so artificial-fertiliser-minded.

The average agriculturist imagines that, when applying sulphate of ammonia, he is replacing the nitrogen that he may have taken from the land in the previous crop. As to whether one is from an organic source, and the other entirely inorganic; as to the possibilities of the natural organic nitrogen being more desirable for the plant than the inorganic—these problems do not occur to him. If he can produce what appears to him to be a useful crop, he is content. Its quality and its life-sustaining abilities—these are no

1. Kaiser, A. D. *Acta pædiatr., Stockh.* 1930, 11, 227.
2. Porter, M. R., Sanders, E. K., Lockwood, J. S. *Ann. Surg.* 1948, 128, 865.
3. Haxton, H. A. *Manch. med. Sch. Gaz.* 1952, 31, 21.

concern of his. Unfortunately, quality in foodstuffs[4] is not recognised in the economic market. Good food sells at the same price as food of indifferent quality; and this makes those farmers who are interested in quality despair of the national mind rising to the position of being able to discriminate between good and bad food.

In my books I have told the story of thirty years of organic farming, and in following this principle I have achieved two ends: (1) an exalted standard of health in my crops and livestock; and (2) more profit in the long run. I do not dismiss labour: on the contrary, I am always seeking to build new and more cottages, and to employ more men. I am content to do this in the full knowledge that human labour is more dependable than machines. The machine still needs a competent man to make it useful. When men are driven from the land, it is always the best man who leaves. It may well be that the greatest curse that has come to our land is mechanisation. The capital sunk is beyond belief; and farmers at the present moment, throughout Britain, are indebted to our banks in a sum of money not less than £200 million. Much of this is due to the purchase of mechanical equipment and artificial fertilisers. The more we mechanise, the further we get away from enduring fertility, and the soil—man's greatest heritage—depreciates.

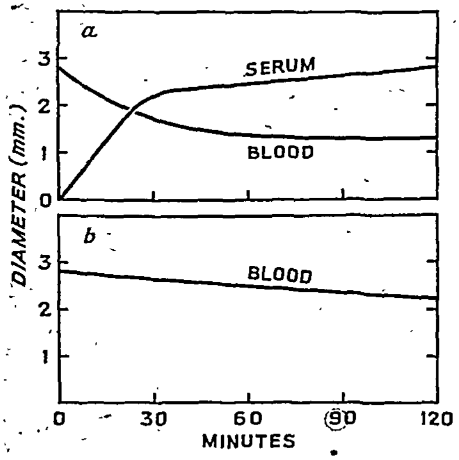
Chute, Andover. FRIEND SYKES.

CLOT RETRACTION

SIR,—Dr. Budtz-Olsen's method of measuring clot retraction, mentioned in your leading article of July 5, is in some ways similar to that recommended in 1948 by Hirschboeck.[1] One of the chief advantages of both methods lies in the fact that retraction is going on in a fluid hydrophobe medium, and so it is not hindered by impurities in badly washed test-tubes, and is not influenced by the varied adsorptive surfaces of different glasses.

The method of Hirschboeck is semiquantitative, establishing only the beginning of clot retraction; that of Budtz-Olsen is superior in this respect, for it measures the quantity of serum extruded in a given period of time. However the Hirschboeck method is a micromethod, needing only one drop of blood—an advantage when dealing with infants and children.

It seems worthwhile therefore to describe briefly a quantitative micro-method which has been evolved along the lines of Hirschboeck and which has been used in our laboratory since 1948. The full details are shortly to be published in the Hungarian journal *Kisérletes Orvostudomány*.



Change in diameter of drop with (*a*) normal blood and (*b*) blood from a patient with thrombocytopenic purpura.

Glass tubes with a flat bottom and a height and diameter of about 1 cm. were selected as containers. 0·02 ml. of blood is slowly blown into these containers on to the surface of some castor oil. The diameter of the blood drop is measured immediately with an ocular micrometer. Taking into consideration the correlation between the enzymatic process of clot retraction and temperature, the container is now placed in a 37°C thermostat, and covered with a cotton-wool cap soaked in water. The diameter of the retracting blood and of the extruded drop of serum are measured after 30, 60, and 120 minutes, and the results are set out graphically.

A typical curve of normal blood with 400,000 platelets per ml. is shown in the figure. After 30 minutes the diameter of the serum drop just exceeds that of the blood. We were able to observe a direct correlation between the number of platelets and clot retraction in the same way as Budtz-Olsen. *A typical curve of a case of thrombocytopenic purpura with* 30,000 platelets per ml. is shown in the figure; here only a very weak retraction occurred during the time of observation, and no serum was squeezed out.

The method is simple and easily reproducible. Knowing the large deviations of platelet-counting methods, we are always checking, in our daily routine examinations, the platelet-counts with clot-retraction measurement. A pathological fall in the platelet-count can be excluded if clot retraction is normal. This method has proved to be extremely useful in classifying the different hæmorrhagic diseases.

CHARGES FOR PAY-BEDS

SIR,—Your leading article last week rightly draws attention to the extravagant charges now made for pay-beds, but I think it omits one important point. The cost of a public bed includes the cost of all medical services, none of which the private patient is using, because normally he pays extra for doctors, X rays, pathological investigations, and even the use of the theatre. By basing his charge on that of a public bed, he pays for these things twice over.

All he really gets for his money is a "hotel" service and the cost of nursing. This hotel service does not have to include many of the amenities, such as dining-rooms, lounges, cocktail bars, and even golf-courses, provided by hotels, and should therefore cost much less than a commercial price in a hotel. Six guineas a week ought to cover it. Add to this a fair proportion of nursing costs, and we should have a reasonable figure which many people would be glad to pay.

Ashtead, Surrey. W. EDWARDS.

FEEDING DISORDERS IN INFANTS

SIR,—I was very interested to read Professor Vining's instructive article (July 19). His submission that "Nature would never have provided an infant with a digestive system so delicately balanced that overfeeding or risk of death from harm or illness produced by the food itself could be a possibility" is, I feel sure, very true. That "starvation and underfeeding in any degree are the dangers most to be avoided" may be equally true.

Is it not possible, then, for scientific knowledge of artificial feeding to be so sound and satisfactory that either of these conditions practically never occurs? The child-welfare clinics and maternity wards are the obvious places to teach mothers in this. Perhaps, too, makers of dried milks might give better-balanced recipes.

I believe that if Dr. Truby King's "fantastic formulæ" were studied, his basic principles would be recognised as true, simple, and uncomplicated. He believed to some degree in "percentage feeding."

It is generally recognised that the healthy underfed baby (if underfeeding is not too prolonged) can be put right much more speedily than the baby whose digestion has been strained and upset by wrong feeding or overfeeding. In the former, there is no digestive disturbance (or "dyspepsia"?) to correct. Generous feeding should be introduced gradually, and if the balance is sound and the ingredients are easy to digest, the baby *will respond well.*

I should never call a mild degree of either underfeeding or overfeeding "dangerous," or even apply the word to wrongly balanced feeding. But if the infant is given no opportunity to recover from any of these faults, his physique may finally be so undermined that he may be in grave danger of catching serious infection.

---

[1] Hirschboeck, J. S. *J. Lab. Clin. Med.* 1948, 33, 347.

The overfed breast-fed baby will generally regulate his feeds himself if allowed to do so, as will the underfed one if he is permitted to feed more often. But the baby on the bottle is much more handicapped.

Whatever name may be given to digestive disorder in artificially fed infants, the cause is practically always the same—a wrongly balanced mixture. It is seldom due merely to underfeeding or overfeeding.

If a baby on a well-proportioned feed, suited to his condition and age as well as weight, and supplying the requisite calories, is obviously hungry, what is more simple and satisfactory than to increase each feed as needed, still keeping the balance correct? Or it may be slightly strengthened for some babies, for their individual needs should be respected. Such a baby does not develop dyspepsia. It is the pathetic infant having over-concentrated feeds (of necessity with too little fluid) who seems to be dissatisfied when the small feed is finished, and, all too often, will later cry with colic and wind, and be generally restless. If his feeding is corrected quickly the normal baby will practically always settle down well, but if his unhappiness is allowed to continue for long it is harder to put right. Fortunately, in most cases where the trouble is ignored, the child will finally settle, but often only after months of misery for both mother and baby.

The fact that a few babies seem to tolerate exceedingly concentrated feeding without wind or colic is not a sound reason for asking them to do so, or for other babies being expected to.

If, unfortunately, breast-feeding should fail, correct bottle-feeding will go a long way to compensate the baby and ensure peaceful and satisfactory progress. Such feeding must be understood and not be experimental.

London, E.C.4. E. MORRISON.

RADIOGRAPHY FOR THE ACUTE ABDOMEN

SIR,—In your annotation (July 5) you say that possibly further study might bring to light additional radiographic signs of intestinal obstruction.

Such a study is at present being carried out at Adeoyo Hospital, University College, Ibadan, Nigeria, where idiopathic cæco-colonic intussusception in young adults is common and presents diagnostic difficulties owing to its resemblance to the dysenteries.

In the cases so far radiographed preoperatively there has been the expected complete absence of colonic gas shadows from the base to the apex of the intussusception, thus producing a uniformly opaque right side of the abdomen, with the distal colon and rectum, if not yet affected, well shown by its gas pattern.

University College,
Ibadan, Nigeria. P. KONSTAM.

BUTAZOLIDINE

SIR,—I wish to add my support of the findings of Dr. Currie and your other correspondents in regard to the use of this substance in the treatment of rheumatoid arthritis.

Therapeutic trial of this chemical in over 40 cases of severe rheumatoid arthritis has been carried out at my hospital clinics at Coventry and Leamington Spa during the past three months, and the results have been most encouraging. Except for one rather severe gluteal abscess in the area of the injection, no unpleasant results have been encountered.

Much smaller doses have been found to be effective than those mentioned by Dr. Currie. Butazolidine 1·0 g. injected intramuscularly twice weekly is the maximum dosage in my series, and in view of the cost of this preparation this smaller dosage may be an important consideration.

The use of butazolidine in rheumatoid arthritis should not prevent us from considering the efficiency of the parent preparation, 'Irgapyrin.' During the past six months over a hundred severe rheumatoid arthritis cases attending my hospital clinics have had treatment with this preparation. In view of the danger of agranulocytosis, blood-counts are made before treatment and after every second injection. The usual course of treatment has been one ampoule of irgapyrin injected once weekly. The sedimentation-rates (Westergren) in severe cases may drop fairly quickly (one patient with Westergren of 96 dropped to Westergren 22 after two injections). Joint swellings and pains are quickly relieved, but there is a tendency to relapse at the end of the course of treatment. For such relapses I use butazolidine and find it very effective.

I have not yet had time to analyse the small proportion of patients who have failed to respond to this combination of drugs, but it may be that for such cases a larger dosage would be effective.

Using irgapyrin to suppress the severity of rheumatoid arthritis and using butazolidine for maintenance purposes, I am convinced that these two drugs can play a most important part in the treatment of this disease.

I am indebted to Pharmaceutical Laboratories Geigy Ltd. for their kindness in giving me supplies of irgapyrin and butazolidine for clinical trial.

JOHN SHULMAN.

Coventry and Warwickshire Hospital, Coventry.
Warneford Hospital, Leamington Spa.

CALCIFEROL IN PULMONARY TUBERCULOSIS

SIR,—Your correspondents, Dr. Randolph White (June 28) and Dr. J. Fielding (July 26), suggest that six weeks of combined calciferol and streptomycin and P.A.S. therapy is too short a course on which to judge fairly the effects of the treatment. I agree that for the sake of completeness it would have been better had a longer course been given. There were, however, good reasons why we did not feel justified in carrying out such a long trial, the most weighty being the risk to the patient of developing streptomycin-resistant strains of tubercle bacilli and thus prejudicing the chances of successful surgical resection at a later date. As reported, 3 of our cases were given a three-month course of 'Sterogyl' (600,000 units weekly), streptomycin, and P.A.S. These cases had extensive bilateral disease where the development of streptomycin resistance would be of no consequence. They showed no unusual response to the extended course of treatment.

Dr. Fielding is not consistent in some of his statements and hypotheses. He holds that the results in the treatment of lupus vulgaris should be a guide to the treatment of pulmonary tuberculous disease, and yet he discontinues his treatment after only four to six months, whereas lupus vulgaris is generally treated for a year or more. Again regarding the histology of lupus lesions treated with calciferol, Dr. Fielding says: "It was this first phase of vascular and exudative reaction which suggested itself as a method of bringing streptomycin to the site of tuberculous lesions otherwise inaccessible."[1] It is known that the phase referred to occurs well within the six weeks' period following the start of calciferol therapy; indeed, careful perusal of Dr. Fielding's cases 1, 3, 5, and 6 (i.e., 4 of the 6 successful results he published) suggests that the dramatic improvement occurred within the first six weeks of treatment. He did refer to the "possibility" of a second healing phase, but apparently the odds have shortened since then.

In empirical methods of treatment of this sort, hypotheses are of little value unless they can be substantiated. If Dr. Fielding is convinced that four to six months of calciferol treatment is of definite value, I hope he will publish the results of an adequate trial with control cases. Our experience at Clare Hall does not encourage us to pursue the matter further.

Clare Hall Hospital,
South Mimms, Barnet. S. L. O. JACKSON.

---

1. Fielding, J., Maloney, J. J. *Lancet*, 1951, ii, 614.

EXTENSIVE RESECTION OF THE SMALL BOWEL

SIR,—In connection with Mr. Johnston's interesting article (April 19), I should like to report the following case.

A girl, aged 10, was admitted to the surgical ward of the Jewish Hospital on Feb. 10, 1951, with vague abdominal symptoms. White blood-cells 7600 per c.mm. (neutrophils 55%); erythrocyte-sedimentation rate (E.S.R.) 5 mm. in first hour (Westergren); fæces negative for parasites. The patient was observed in hospital for five days.

On March 2 the patient was readmitted. She now had an acute abdominal condition, with vomiting and greater tenderness in the upper abdomen. White blood-cells 23,850 per c.mm. (neutrophils 90%); E.S.R. 17 mm. in first hour.

A median laparotomy, performed without delay, yielded turbid fluid from the peritoneal cavity. A large portion of the small intestine was found to be gangrenous, owing to invagination; and the mesentery was extremely œdematous. Complete disinvagination proved impossible; and 90 in. of the small bowel was resected, with end-to-end anastomosis. The invagination was found to be due to a large papilloma.

After the critical first three days, the patient's condition gradually improved and she made an uninterrupted recovery. She left hospital on April 7, apparently none the worse for the extensive operation. She was passing two stools per day, the fat-content of which was not increased; and there were no indications of any physical after-effects, weight and growth being apparently unaffected.

According to Rolssen the small bowel in a child of 10 is about 160 in. long. The absence of disturbance after the operation is no doubt explained by Flint's[1] observation (cited by Mr. Johnston) that in dogs submitted to enterectomy the remaining bowel increased in diameter to about twice the normal, and the absorbing surface increased by 400%.

Cairo, Egypt. H. PICARD.

Medicine and the Law

Appeal from the G.M.C.

THE first of the appeals from the Medical Disciplinary Committee to the Privy Council has now been disposed of, and we have as yet (unless the judgment contained much more than has hitherto been reported) no strong impression of the difference that the new statutory right of appeal will make.

The name of Dr. Daly, who appeared in person, was to be erased, under section 29 of the Medical Act, on the ground of his misconduct with a woman who was his patient. His explanation of how he came to fall in love with her could not greatly help him. He contended that the determination of the Medical Disciplinary Committee was influenced by the admission of evidence of his previous career. It was pointed out to him that the committee was not informed of the previous history until it had come to its conclusion on the facts of the case. It was then proper for the committee to have the information before it decided upon the nature of the penalty. As Lord Tucker observed, if the previous history of a practitioner has been entirely blameless, it would be important and advantageous for the committee to know the position. The Privy Council dismissed his appeal.

Does the concession of a right of appeal to Her Majesty in Council under section 20 of the 1950 Act really make any difference at all? When the Act of 1858 was passed, the courts refused to go into the merits of the doctor's case. They have been ready to intervene if the domestic tribunal acted without the "due inquiry" which the 1858 statute required, if there was no evidence on which the tribunal could erase a name from the register, if the decision was corrupt, or if some member of the tribunal sat when disqualified. These grounds for intervention have seldom been established; they are even less likely to exist today. The General Medical Council (now replaced by the Medical Disciplinary Committee) was declared in Ex parte la Mert (1863) to be the judge whether the medical practitioner on the register had been guilty of infamous conduct. It was not, said the judges in Leeson's case in 1889, a question for the court whether the council arrived at the right conclusion. "We have not," said the court in Allinson's case in 1894, "to say whether the Council were right or wrong in the inference which they draw." Must not the new appellate tribunal follow the same line?

Long-range Shock

The law-courts have long recognised that mental shock without physical impact was a form of injury for which a defendant, if found at fault, may have to pay damages. "It is now settled," said Lord Thankerton in Bourhill *v.* Young (1942), "that such injury includes injury by shock although no direct physical impact or lesion occurs." "The distinction between mental shock and bodily shock," said Lord Macmillan in the same case, "was never a scientific one." One of the earliest decisions for this purpose was the award of damages against a practical joker who frightened a woman with false information that her husband had met with a serious accident. Lately, in King *v.* Phillips,[1] it has been established afresh that there is a geographical radius within which the cause of the shock must arise. Mrs. King, looking out of her upstairs window, heard a scream from the end of the road. She recognised it as the cry of her 5-year-old son, and she saw a taxicab backing on to his tricycle. She saw the tricycle under the cab, but could not see the boy. Eventually she met him running home. Mr. Justice McNair awarded £5 for the not very serious harm to the boy and £10 for the value of the destroyed tricycle. But he found himself unable to award damages to the mother who had subsequently suffered from nervous shock and trembling fits. Like any normal mother, he said, she was anxious for the safety of her child, but she had no special susceptibility to shock. The driver of the cab was not liable for shock unless the injury was within what he ought to have reasonably contemplated as the area of potential danger arising from his negligence. The mother was 70 to 80 yards away from the scene of the accident, "wholly outside the area or range of reasonable anticipation." The learned judge declared it was contrary to common sense to say that a taxi-driver, backing his cab without looking where he was going, ought reasonably to have contemplated *that* he might cause injury by shock to a woman in a house so far away up a side street.

The high-water mark of successful claims in this type of case was Owens *v.* Liverpool Corporation (1939), where the corporation's tramcar collided with and damaged a hearse and overturned the coffin. Mourners following in the funeral procession were held entitled to damages for mental shock. But in the Bourhill case, already cited, the House of Lords rejected that kind of claim. There a motor-cyclist, riding at an excessive speed, collided with a motor-car and was killed. A woman 45 feet away (on the other side of a tramcar) heard the noise but did not see the accident. She suffered fright, but admittedly not from any fear of danger to herself. She was 8 months pregnant and her child was stillborn. Their Lordships asked what ought the motor-cyclist to have contemplated, as a reasonable man, as the area of potential danger arising from his negligent riding. The woman on the other side of a tramcar, they held, was not within that area. The law, it seems, is obliged to attribute even to careless persons a degree of cool ratiocination which they are scarcely likely to have reached. The geographical limitation may furnish as good a test as anything else; but, if he really does apply his mind to such speculative calculation, where, in these days of television, is the too speedy motor-cyclist to draw the line?

Cost of Burying Hospital Patient

In Scotland a county council has been held liable to pay for the burial of a patient who died in hospital and whose relatives could not be traced.[2] Apparently the county council was asked to bury him but refused. Burial was then carried out on the instructions of the Secretary of State for Scotland, who sued the county council for the funeral expenses. In the sheriff court the judge found himself obliged to conclude that, whereas the State provided for the health of the living, not only during life but before birth, its obligation ceased on the death-bed. It may have been material that county councils, being bodies corporate, are specifically barred from claiming death grants under the National Insurance Act.

Public Health

Poliomyelitis

POLIOMYELITIS notifications in the week ended July 26 (the 30th week of the year) were (previous week in parentheses): paralytic, 157 (104); non-paralytic, 96 (59): total, 253 (163).

The following table compares this year (up to and including the 30th week) with the preceding five years.

Year	*Total cases up to and including 30th week*	*Cases in 30th week*
1947	1141	336
1948	830	39
1949	1016	169
1950	2226	306
1951	1282	121
1952	1430	253

Up to and including the week ended July 26 the over-all notification-rate for England and Wales was 3·26 per 100,000 population.

The districts which have notified 10 or more cases up to July 26, with incidence per 100,000 population, are:

District or borough	*Total cases*	*Incidence*
Gateshead	63	54·9
Felling	26	103·2
Whickham	13	61·0
Southend-on-Sea	10	6·6
Liverpool	26	3·3
Manchester	24	3·4
Fulham	10	8·2
Wandsworth	15	4·5
Woolwich	20	13·3
Ealing	14	7·5
Harrow	13	5·9
Newcastle upon Tyne	43	14·7
Yeovil	18	102·9
Blyth (Suffolk)	13	50·0
Birmingham	47	4·2
Coventry	11	4·3
Malvern	10	51·1
Leeds	48	9·5
Sheffield	14	2·7
Cardiff	16	6·6

The regional notification-rates and incidence per 100,000 population (up to and including week ended July 26, 1952) are:

Region	*Paralytic*	*Non-paralytic*	*Total cases*	*Incidence*
Northern	133	128	261	8·3
East and West Ridings ..	124	23	147	3·6
North-western	88	28	116	1·8
North Midland	22	34	56	1·7
Midland	85	42	127	2·9
Southern	61	27	88	3·3
South-western	58	42	100	3·3

Tuberculosis Figures for Manchester

In his report for 1951 Dr. C. Metcalfe Brown, medical officer of health for Manchester, draws attention to an increase in pulmonary tuberculosis in children under the age of five. In the past five years there have been 2½ times as many notifications in this age-group as in the preceding five years, and nearly 4 times as many as in the five years before the outbreak of the late war. The reason, he thinks, can only be that, though the waiting period for institutional treatment has been considerably reduced, the delay is still too long, and young children with poor immunity continue to be exposed to infectious people. But the notification-rate for non-pulmonary tuberculosis in this age-group in Manchester has again declined; and the mortality of both pulmonary and non-pulmonary tuberculosis in the whole population has also decreased since 1950. The death-rate from respiratory disease was 0·45 per 1000 population (0·58 in 1950), and for non-respiratory disease 0·06 per 1000 population (0·07 in 1950).

The infant-mortality rate in 1951 was the lowest ever recorded in Manchester—35·3 per 1000 live births. The corresponding figure for 1950 was 37·9.

Parliament

Foot-and-mouth Disease

REPLYING to a debate in the House of Commons on the adjournment for the summer recess on Aug. 1, Sir THOMAS DUGDALE, Minister of Agriculture, said the departmental committee, which the Government were setting up to review policy for foot-and-mouth disease, would start work in the autumn under the chairmanship of Sir Ernest Gowers.

There were, he continued, 22 outbreaks in the second half of July compared with 29, 43, and 63 in the previous half-monthly periods. Since Nov. 14 last year, when the first outbreak of the present series occurred, there had been 548 outbreaks. This had entailed the slaughter of just over 36,000 cattle, 37,000 sheep, and 11,500 pigs. In Western Europe, the position had also improved since the winter and spring. In the Scandinavian countries and in Holland and Belgium there had been relatively few outbreaks since the beginning of June. The one exception to the general improvement—and it was serious—was France, where the position was still deteriorating. Fortunately for this country, the infection now appeared to be moving away from those parts of France nearest to our coasts, and there was no evidence that fresh infection had been introduced into this country from France since the end of June. Although his veterinary advisers would like a little longer experience before advising a change, he hoped that the controlled area in Southern England might be removed in the fairly near future.

Closed Shop Dispute

In answer to a question, Sir WALTER MONCKTON, Minister of Labour, said that he had now received the award of the board of arbitration appointed to determine the difference between the Durham County Council and the Joint Emergency Committee of the professions. He said that differences between the county council and some of their professional employees had persisted for a considerable time. The present difference arose over the county council's regulation that applications for extended sick-pay must be made by or through a trade union or other appropriate organisation. At the request of the parties he appointed a board of arbitration and the parties undertook in advance to accept and implement any award made by the board. Both parties accepted that as far as certain professions were concerned membership of a trade union or professional organisation should not be imposed as a condition of employment. The agreed terms of reference accordingly included the question whether the present regulations of the council governing the making of applications for extended sick-pay were in conflict with the principle of voluntary membership of a trade union or professional organisation and should therefore be withdrawn. The board's award was that in so far as the regulations required such applications to be made through a trade union or other appropriate organisation they were in conflict with that principle and should be withdrawn.

Hypnotism Act

On Aug. 1, in the House of Lords, the Royal Assent was given by Commission to the Hypnotism Act.

---

[2] *Scotsman*, July 12, 1952.

QUESTION TIME

Pasteurisation of Milk

Replying to a question, Dr. CHARLES HILL, parliamentary secretary to the Ministry of Health, said that 82% of all milk sold in the liquid market in England and Wales and 73% in Scotland was already pasteurised or sterilised, and that these percentages would gradually be improved. None of this milk was mixed with other milks before sale.

Prescription Forms

Mr. V. F. YATES asked the Minister of Health if he was aware that there was considerable discrepancy in the practice of doctors as to the number of prescriptions they put on one form; and if he would alter doctors' terms of service to ensure that greater conformity was reached in this respect.—Mr. IAIN MACLEOD replied: The need may vary in different cases. I am not clear that it would be an advantage to import further requirements into doctors' terms of service.

Hospital Waiting-lists

In answer to a question Mr. MACLEOD stated that the waiting-list for hospital patients was 503,584 on Dec. 31, 1951.

Bone-conduction Hearing-aids

In answer to a question Mr. MACLEOD stated the Electro-Acoustics Committee of the Medical Research Council had now assessed the results of clinical trials of an experimental bone-conduction aid produced for the National Health Service. The committee had recommended this aid for issue to patients for whom a bone-conduction aid is more suitable than an air-conduction aid and he was arranging for large-scale production as soon as possible.

Spectators at Operations

Mr. E. W. SHORT asked the Minister why an American music hall artiste was recently allowed to be present at an operation at the Royal Victoria Infirmary, Newcastle upon Tyne.—Mr. MACLEOD replied: The incident is shortly to be considered by the board of governors.

Mr. SHORT: Has the Minister taken adequate steps to see that this method of entertaining music hall comedians does not spread to other cities?—Mr. MACLEOD: It is a little unfair to leave it at that. The responsibility for admission will, of course, be decided and reported to me, but the person in question—Mr. Danny Kaye, as the hon. member knows—was properly masked and properly gowned, as one would expect.

Mr. M. A. LINDSAY: Is there any reason why any person, irrespective of nationality or sex, should not watch an operation if invited to do so by the surgeon?

Mr. G. R. CHETWYND: As the facilities were given to Mr. Kaye to see the opening of the patient, were any facilities given to the patient to see the opening performance of Mr. Danny Kaye?—Mr. MACLEOD: The patient, in any case, has recovered.

Appointments

BRUNNEN, P. L., M.B. Aberd., F.R.C.S.: *consultant thoracic surgeon*, North Eastern Regional Thoracic Surgery Unit, Scotland.

* LECKIE, F. H., M.C., L.R.C.P.E., M.R.C.O.G.: asst. obstetrician, East District Hospital and Glasgow Royal Infirmary.

LEWIS, W. J., M.R.C.S., D.A.: consultant anæsthetist, Mid-Glamorgan H.M.C.

SINCLAIR, W. W., M.B. Glasg., D.P.H.: senior school M.O., County of Fife.

WISE, LIONEL, M.B., B.SC. Manc.: whole-time consultant pathologist, Wrexham H.M.C.

Colonial Service:

ARMSTRONG, R. F., L.R.C.P.E.: M.O., Tanganyika.
CLARK, J. S., M.B. Durh.: M.O., Nyasaland.
EDDY, T. P., M.R.C.S., D.P.H.: A.D.M.S., Sierra Leone.
GROSS, R. D., M.D. Lond., D.P.H.: D.D.M.S., Federation of Malaya.
HADMAN, D. F., D.S.C., M.B.: resident M.O., Kenya.
HAYNES, W. S., M.D. Camb.: tuberculosis officer, Kenya.
HOLMES, A., M.B.: M.O., Nyasaland.
JOHNSON, A. J., M.B. Camb., D.T.M. & H.: D.D.M.S., Sierra Leone.
JONES, S. H. O., M.B. Manc., D.T.M. & H.:
LINSELL, C. A., M.B.: resident M.O., Kil
Kenya.
MACPHERSON, J. J., F.R.C.S.E.: M.O., Federation of Malaya.
PRICE, P. B. W., M.B. Calcutta: M.O., Seychelles.
ROBSON, J. R. K., M.B. Durh.: M.O., Tanganyika.
WARMANN, J. St. G., M.R.C.S., D.P.H.: M.O.H., Nigeria.

* Amended notice.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Obituary

GEORGE CARMICHAEL LOW

M.A. St. And., M.D. Edin., F.R.C.P.

Dr. Carmichael Low, formerly director of the division of clinical tropical medicine at the London School of Hygiene and Tropical Medicine, died at his home in London on July 31. He was in his 80th year, and he had lived through a fruitful and revolutionary period of medical progress, to which, through his work in tropical medicine, he had substantially contributed.

He was born at Monifieth, Forfarshire, and from Madras College, St. Andrews, he went to Edinburgh University, where he graduated M.B. with first-class honours in 1897. Soon after he had done his house-jobs at the Edinburgh Royal Infirmary the fame of Manson, who was then creating his school of tropical medicine, drew him to London. Manson soon settled his career for him by sending him to Heidelberg and Vienna to learn, among other things, the new technique of sectioning mosquitoes in celloidin by a sliding microtome. At this time progress in studying the development of parasites in mosquitoes had been halted by the difficulty in making sections, because paraffin is unsuitable.

[Haines

It so happened that at the time of Low's return Manson had received a collection of alcohol-preserved mosquitoes (*Culex fatigans*), which had been fed on filaria-infected subjects, in Brisbane, Queensland. Low was given the task of sectioning these insects—and he performed it so effectively that almost in the first specimen he was able to demonstrate the filaria passing down the proboscis sheath of the insect and emerging at the tip. His report on this work, published in the *British Medical Journal* in 1900, proved conclusively that the insect conveyed the infection to man in the act of biting—a method which for some reason had never been apparent to Manson before and which pointed the way to the transmission of malaria as well. This important work was soon confirmed independently by S. P. James working in isolation in Travancore, India.

In 1900 Low was sent by Manson to Ostia on the Roman Campagna, where a mosquito-proof hut had been erected in the most malarious spot. There, in company with Dr. L. W. Sambon and the artist, Signor Terzi, he spent the next three months in the epidemic season. Low, who was in command, shepherded his charges into the hut every evening and shut them up behind mosquito-netted windows and doors for the night. All around them Italian peasants and Red Cross workers lay fever-stricken in their huts; but Low and his party remained unscathed. They were visited by Professor Grassi, who was making his historic researches into the transmission of malaria, and at Ostia the mosquitoes were collected which later were injected with malaria parasites in Rome and despatched to London to bite Manson's son (P. T. Manson) who in due course developed malaria.

Low's next assignment was to the West Indies where he was appointed *Cragg's scholar* for the study of filariasis in those islands. By this work he was also able to demonstrate the relation of *Wuchereria bancrofti* to elephantiasis and the part played by *Mansonella demarquayi* and *M. ozzardi* among the Amerinds of British Guiana.

On his return from the Caribbean Low was appointed, at Manson's instigation, to the Royal Society's mission to Uganda (1903) where a severe epidemic of sleeping-sickness had broken out and it was necessary to assess the relation of the recently discovered *Trypanosoma gambiense* to the mysterious "Negro lethargy." Low was especially interested in the Central African filaria, then known as *Filaria perstans* (now *Acanthocheilonema perstans*), and he worked hard to prove its association—which Manson suspected—with sleeping-sickness.

As an outstanding figure in the new science of tropical medicine, Low was the obvious choice when the post of superintendent of the Tropical School in the Albert Dock fell vacant. He proved a good teacher and organiser and held this appointment for the rest of his professional life. He was always ready to spend hours on any necropsy of tropical importance, and that he found much to interest him is shown by the number of papers he wrote. This side of his work led to his appointment as pathologist to the West London Hospital.

To Low belongs the credit of the creation of the Royal Society of Tropical Medicine in 1907 and of housing it in Manson House, its present headquarters, in 1930. It may be claimed that without him there would have been no society, because for many years he carried the burden almost unaided. He was secretary from 1912 to 1920 and president for the unprecedented period of four years from 1929 to 1933. He was most generous to the society and his gifts included the magnificent rostrum which now adorns Manson House.

During the first world war Low, with the rank of major in the I.M.S., was responsible for the treatment of officers from India suffering from tropical disease, and with Wenyon and Clifford Dobell he began to make a special study of amœbiasis. When the Hospital for Tropical Diseases and the London School of Tropical Medicine were moved to the centre of London he became the senior physician to the hospital and director of the clinical division of the newly constituted School of Hygiene and Tropical Medicine in its new quarters. There he continued to lecture and teach till his retirement in 1937.

Low's interests were not bounded by his specialty, and the naturalist latent in him came to the fore in his closing years. He was a good and deeply read ornithologist, and he was one of the group of bird-watchers who at Staines and other reservoirs put London ornithology on the map. He was the official bird-watcher in Kensington Gardens and for many years secretary and treasurer of the British Ornithologists Club. He was also a member of the council of the Zoological Society and he was responsible for the volume on *Aves* at its centenary in 1929. Of late years his was a well-known figure in the bird room at the South Kensington Museum. His chief contribution to ornithology was his bibliography, the *Literature of the Charadriiformes*, which reached a second edition in 1931.

Among many honours Low received the Straits Settlements gold medal from the University of Edinburgh in 1912, and the Mary Kingsley medal in 1929. He was also corresponding member of the Société de Pathologie Exotique of Paris and an honorary member of the Belgian Society of Tropical Medicine. He was elected F.R.C.P. in 1924. He collaborated with Sir Neil Hamilton Fairley, F.R.S., in the tropical section of Price's *Textbook of Medicine* and with Dobell on amœbiasis in Byam and Archibald's *Practice of Medicine in The Tropics*.

P. H. M.-B., to whom we are indebted for this memoir, adds :

> Low had a brand of dry Scottish humour, all the more apparent because it was often unconsciously expressed. For this reason, and for the exposition from time to time of priceless principles which he enunciated for himself, his lectures were always a source of attraction and entertainment. Few will ever forget the sideways glance of his eye, the knowing and ever-recurring head-nod, and his Celtic ejaculation of "Eh-Eh." With all these attainments and characteristics he was a kindly soul who was ever interested in the doings of young people—among whom he would include his professional colleagues—and he was especially attracted to birds, animals, and dogs. I was associated with him for over forty years, and in saying goodbye to an old and valued colleague I feel I am taking farewell of the generation that he represented so well.

Dr. Low married in 1906 Edith, daughter of Mr. Joseph Nash. There were no children of the marriage.

LESLIE CUNNINGHAM

M.A., M.B. Camb., F.R.C.P.

Dr. Leslie Cunningham, physician to the David Lewis Northern Hospital, Liverpool, died on July 30 at the age of 59.

A foundation scholar of Downing College, Cambridge, he took his tripos in 1914. When war broke out he completed his medical studies as quickly as possible, and qualified M.R.C.S. from St. Bartholomew's Hospital two years later. After serving in the R.A.M.C., with the rank of captain, he took his M.B. in 1921 and his M.R.C.P. in 1923. He held several resident appointments at the David Lewis Northern Hospital in Liverpool, and when later he settled in consultant practice in Liverpool he was appointed to its staff. In due course he also joined the staff of the Birkenhead General Hospital and the Ormskirk General Hospital. In 1942 he was elected F.R.C.P.

R. E. writes : "Cunningham belonged to the ever-dwindling clan of general physicians, and his wide medical interests and sound judgment helped to make him one of the most sought-after consultants on Merseyside. Small of stature and rotund of figure, he was calm and unhurried, and entirely free from airs and graces and frills, with an endearing chuckle that could become a paroxysm of mirth. Like most rather silent men, he was not easy to know, and I think it is true to say that no-one ever knew what L. C. was really thinking. This capacity for silence made him a rather terrifying figure to his juniors, and certainly his nursing staffs were always very much on their toes at his outpatients and ward rounds. But he was beloved and respected, and the large gathering at his funeral service was testimony to his universal popularity. Cunningham was always a popular teacher with students ; there were no fireworks, but a dignified and sound exposition of clinical medicine, leavened with unexpected sly humour.

"Despite his distinctly unathletic build, until recent years Cunningham was no mean player of tennis and golf ; on the tennis-court he was always to be found in the most suitable place to hit a ball, and his golf was of the shortest-path-to-home variety."

Cunningham married rather late in life, but his family life at Prenton was ideally happy, and he was devoted to his young family. He leaves his widow with five children.

Births, Marriages, and Deaths

BIRTHS

DODS.—On Aug. 1, at Bulawayo, Southern Rhodesia, to Noel (née Gilbert), wife of Dr. A. S. Dods—a daughter.

LEWIS.—On Aug. 3, at 106, Stroud Road, Gloucester, to Johanne (née Marcussén), the wife of Dr. Ninian Lewis—a son.

OWEN.—On July 29, to Barbara (née Lewis), wife of Mr. Kenneth Owen, F.R.C.S. of 98, Longmore Avenue, New Barnet—a daughter.

READ.—On July 25, at the Middlesex Hospital, to Ann, wife of Mr. Keith Read, M.R.C.O.G.—a son.

TEMPEST.—On July 26, at St. James's Hospital, Leeds, to Jean Elisabeth (née Turner), wife of Mr. Michael N. Tempest, F.R.C.S.—a daughter.

MARRIAGES

HERDMAN—HOWARTH.—On July 30, in London, Gawin Joseph Seaton Herdman, M.B., to Betty Eileen Howarth, M.R.C.P.

NEWMAN—SANDISON.—On July 26, at Kensington, Graham R. Newman to Joycelyn H. W. Sandison, M.B.

ROGERS—AINSLEY.—On July 30, in London, Lambert Rogers, F.R.C.S., professor of surgery, University of Wales, to Barbara Mary Ainsley.

SOLOMONS—MAITLAND.—On July 29, Michael Solomons, M.B., of Dublin, to Joan Maitland.

DEATHS

ANDERSON.—On Aug. 1, at Greenacres, Wootton Courtenay, Somerset, Kenneth Anderson, M.B. Lond.

BROWNE.—On July 24, in Dublin, O'Donel Thornley Dodwell Browne, M.B. Dubl., F.R.C.P.I., F.R.C.O.G., master, Rotunda Hospital.

CUNNINGHAM.—On July 30, Leslie Cunningham, M.A., M.B. Camb., F.R.C.P., of Rodney Street, Liverpool.

GARNETT PASSE.—On Aug. 1, Edward Roland Garnett Passe, F.R.C.S., F.A.C.S., of Weymouth Street, London, W.1.

HENDERSON.—On July 31, at Coldstream, John Henderson, M.B. Edin.

LOW.—On July 31, at 7, Kent House, Kensington, W.8, George Carmichael Low, M.A. St. And., M.D. Edin., F.R.C.P.

MORRIS.—On Aug. 2, John Morris, M.R.C.S., of Park Avenue, Newport Pagnell, Bucks, aged 71.

News

University of Oxford

On July 19 the following degrees were conferred:

D.M.—J. M. K. Spalding.

B.M.—M. J. A. Davies, P. J. R. Phizackerley, D. R. Oppenheimer, W. D. Hayley, R. T. H. Shepherd, M. A. Smith, M. S. Finn, D. G. H. Patey, R. M. Murray-Leslie, J. M. H. Brooks, A. T. N. Fletcher,
R. A. [illegible] Viscount Suirdale, E. D. R. Campbell,
N. J. [illegible] J. W. P. Bradley, C. W. H. Havard,
J. E. [illegible] Davies, J. C. [illegible]
Mitch[illegible] Wilson, Carm[illegible]
Feldberg, Felicity C. Toussaint, *H. G. Klem.

* In absentia.

Royal College of Physicians of London

At a comitia of the college held on July 31, Sir Russell Brain, the president, announced that H.R.H. the Duke of Edinburgh had accepted the honorary fellowship of the college.

The following fellows were elected officers for the ensuing year:

Censors: Dr. A. H. [illegible]
Lee Lauder, Dr. J. R. H. [illegible]
Registrar: Sir Harold [illegible]
Dodds. *Assistant registra*[illegible]
Prof. J. H. Dible, Dr. F[illegible]
Fox. *Finance committee* [illegible]
Dr. A. D. C. Bell.

The following were elected examiners:

Chemistry: Mr. A. E. Kellie, PH.D., Mr. George King, D.SC. *Physics:* Mr. H. F. Cook, PH.D., Prof. Joseph Rotblat, D.SC. *Materia medica and pharmacology:* Dr. W. N. Mann, Dr. C. J. Gavey, Dr. J. F. Dow, Dr. H. C. Stewart, Prof. J. H. Burn, Prof. J. M. Robson. *Physiology:* Prof. R. J. S. McDowall, Prof. W. R. Spurrell. *Anatomy:* Prof. James Whillis. *Pathology:* Prof. L. P. Garrod, Prof. T. F. Hewer, Dr. Arthur Willcox, Dr. L. C. Martin. *Medical*
anat[illegible] *edicine:* Dr. W. G. Wyllie,
Dr. [illegible] n, Dr. H. K. Goadby, Prof.
S. J. [illegible] Clifford Hoyle, Dr. W. D. W.
Bro[illegible] . V. Neale, Dr. J. F. Stokes,
Dr. [illegible] *diseases peculiar to women:*
Mr. [illegible] Mr. K. V. Bailey, Mr. Ian
Jack[illegible] *: Part I,* Dr. N. M. Good-
man, [illegible] *Tropical Medicine: Clinical*
tropical medicine and medi[illegible] Sir George McRobert;
Tropical hygiene Dr. R. F. [illegible] . A. J. B.

Read, M.B. Lond., A. C. Ronald, M.B. Cape Town, J. D. Sheehan, M.B. N.U.I., R. G. Shorter, M.B. Lond., J. P. Stanfield, M.B. Lpool, P. G. I. Stoven, M.B. Camb., C. G. A. Thomas, B.M. Oxfd, G. W. Thorpe, M.B. Birm., A. L. Turnbull, B.M. Oxfd, Walter van't Hoff, M.B. Camb., R. H. C. Wells, M.B. Lond., D. M. Williams, M.B. Wales, P. O. Williams, M.B. Camb., M. F. T. Yealland, M.B. Camb.

Licences to practise were conferred upon 129 candidates (104 men and 25 women) who have passed the final examination of the Conjoint Board:

Vincent Ainsworth, A. L. Bass, I. S. Batey, K. B. Bender, Anthony Betts, M. H. H. Bishop, June E. Brett, J. R. Brown, J. W. Brown, C. C. Bull, G. M. B. Bulman, A. R. Butterfield, G. R. C. Campion, Harold Caplan, D. A. Chiswell, J. A. Clappen, B. J. F. Coles, H. A. Collins, Betty R. Corbin, H. J. E. Cox, H. F. Crawford G. T. Crook, R. L. E. Cumberbatch, Bethan Davies, E. P. Denton, J. M. Dolphin, Aileen B. Donnison, A. K. Dowle, Michael Dulake, W. F. Dummer, A. V. Dunlop, B. A. East, T. A. Evans, N. H. Eve, F. W. Fairhead, K. T. Farn, P. M. Forster, J. L. Fraser, A. G. E. Fung-a-Fat, D. R. Gamble, Mary J. Gibbons, Basil Gilbert, I. L. Glaisher, H. W. Goldfarb, J. H. Goode, Kenneth Grainger, Bernadette Gregory, Joan E. Hancock, R. B. Handscombe, N. B. Harris, J. D. Harte, W. D. Hayley, D. A. Heath, E. R. Herst, F. E. Hill, C. B. Hodes, Vera M. C. Hollyhock, Blanche M. Hooper, Shirley E Hoyes, K. R. Hughes, J. P. Hurrell, G. H. Jeavons, R. D. Jones, A. F. Jordan, Leonard Kader, E. E. F. Keal, D. J. Kidd, D. W. G. King, Iris M. Krass, C. G. Lambert, R. J. W. Lambert, Lian Heng Lee, Fred Lees, K. M. M. Lewis, Harry Lindsay, Patricia M. Lumb,
Nancy S. Maguire, George Mangan, R. [illegible]
Marjot, Philippa M. Martin, J. A. Mea[illegible]
Morley, Yusuf Adam Motala, J. H. [illegible]
Kathleen M. Neville, Elizabeth C. [illegible]
W. N. B. Parker, W. P. Pereira, Mary E. R. Perry, R. J. V. Peter, R. A. N. Petrie, E. M. Pilkington, L. J. Posener, L. B. Prescott, M. N. Prichard, Freda E. Prince-White, F. C. Ramsey, G. L. S. Rankin, Shelagh M. Richards, G. G. Robbie, T. E. Roberts, Winifred M. S. Robinson, Vera Rose, Guy Screech, D. B. Shaw, Kenneth Shiffman, D. N. Sinclair, J. J. Slome, Isabel G. Smith, J. L. Stevenson, Mary L. Stewart, J. L. Szentpétery, Elizabeth A. Thomson, G. N. W. Tilsley, David Tingle, G. R. P. A. Vernon, Peter Wallis, A. W. Warltier, P. A. Watt, Joyce D. Waye, E. A. Wilson, P. G. Woolf, J. G. Wotherspoon, S. S. Young.

Diplomas were conferred on those named in the reports of meetings of the Royal College of Surgeons in our issues of June 21 (p. 1265) and July 19 (p. 151). The following diplomas were also conferred:

D.P.H.—Margaret A. M. Howard, F. X. Letellier, R. L. Lindon, J. F. McGovern, Manshanker Laxmishanker Rawal, G. M. Reynolds, Mary M. E. Rutter, Malati Shrinagesh, Irshad Husain Syed.

D.O.—Narindar Singh Batheja, R. D. Calcott, Brojo Mohon Chatterjee, G. V. Cole, P. H. Cowen, Rowland Cowley, C. W. L. Crawford, E. B. Doany, Stella P. Eadie, Margaret Ford, Hamish Fraser, S. D. Gun-Munro, Mohamad Habibulla, James Hughes,
I. G. Johnst[illegible] Joseph, P. J. Mathews, Jean
C. I. Melville [illegible] . N. Ormrod, J. A. E. Primrose,
Anjani Kum[illegible] Sud, J. E. Thomas, Raymond
Traill, C. G. [illegible]

D.I.H.—A[illegible] . W. McConnachie, Sardari Lal Malhotra, Manchsnker Laxmishanker Rawal, J. F. Skone, W. C. Turner, M. D. Warren.

Royal College of Surgeons of England

At a meeting of the council on July 31, with Sir Cecil Wakeley, the president, in the chair, Dr. O. C. Carter and Dr. Bernard Johnson were admitted to the council. Mr. R. C. Davenport and Mr. F. C. W. Capps were elected members of the court of examiners. Prof. F. Wood Jones was appointed to the post of honorary curator of the Hunterian collection of human and comparative anatomy on his retirement from the Sir William Collins professorship of anatomy. The Hallett prize was awarded to Dr. J. K. Ross (Middlesex Hospital).

It was decided that as from Jan. 1, 1954, the period of postgraduate surgical training in recognised posts required of candidates for the final fellowship examination should be increased to two years.

Diplomas of fellowship were granted to D. I. Stirk and G. Westbury.

Diplomas of membership and postgraduate diplomas were granted to the candidates named above in the report of the comitia of the Royal College of Physicians.

Royal Institute of Public Health and Hygiene

The institute holds courses of instruction for the certificate and diploma in public health, and the diploma in industrial health. Further information may be had from the secretary of the institute, 28, Portland Place, London, W.1.

CORRIGENDA: *Salt-retaining Adrenal Hormone.*—In the paper by Mrs. Simpson, Dr. Tait, and Mr. Bush (Aug. 2, p. 226) the first sentence under the heading *Results* should read: "The results of the assay when applied to the extract of monkey adrenal blood are given in table I." The footnote to table I should read: "1 ml. of the adrenal extract employed was equivalent to 140 µg. of deoxycortone acetate." In table II the actual mineral activity found in the corticosterone region (fraction 4) lay between 0 and 15 µg. of deoxycortone acetate.

Paratyphoid-B Fever in Cardiff.—In our note under "Public Health" published on July 19 the infecting organism should have been described as "paratyphoid-B bacillus, Vi-phage type 1."

IMMUNITY TO VIRUSES

A GENERAL DISCUSSION WITH SPECIAL REFERENCE TO THE RÔLE OF ALLERGY[*]

W. I. B. BEVERIDGE
M.A. Camb., D.V.Sc. Sydney
PROFESSOR OF ANIMAL PATHOLOGY IN THE UNIVERSITY OF CAMBRIDGE

THE degree of immunity evoked by viruses varies greatly from one disease to another. It would be useful if we could explain why some diseases are followed by a lifelong immunity whereas others seem to confer no immunity.

In looking for general principles it is often helpful to start by assembling the data and attempting some form of classification. I therefore propose classifying virus diseases according to type of immunity following a natural attack.

In class I I have placed those diseases which evoke what I shall call a first-class immunity, that is, an immunity which is dependable and endures for many years and even for life; recovery is usually accompanied by disappearance of the virus, except perhaps in occasional carriers, and relapses are rare. In class II are those diseases which produce a second-class immunity; repeated attacks of these diseases are common, even at short intervals, but again the virus is usually thrown off on recovery and relapses are unusual. A third-class immunity is the state in which the virus is not thrown off for some months or perhaps never, and in which relapses or persistence of the lesions are common; if the virus is eventually thrown off immunity is not usually solid.

Table I shows the best-known virus diseases of man and domestic animals classified according to these criteria. It is not possible to fit all known virus diseases into one of these three groups, because our knowledge of some of the diseases is too scanty. There is also the difficulty that complex biological phenomena do not lend themselves to rigid classification. But I think some simplification and approximation is justifiable so long as one bears in mind that placing two diseases in the same group does not imply complete identity in the type of immunity each produces.

Let us examine these groups of diseases and attempt to define the factors determining such widely different types of immunological behaviour.

VIRUSES PRODUCING A FIRST-CLASS IMMUNITY

All the class-I diseases are systemic infections running a rapid course. They do not have a chronic phase. Recovery is usually followed by elimination of the virus, or at any rate the virus can no longer be detected. The carrier state is found in only a few of these diseases—notably in infectious laryngotracheitis—and even in this disease only a small proportion of recovered animals continue to harbour the virus and they show no evidence of it. Relapses shortly after the first febrile attack subsides do occur occasionally in some of these diseases but generally are rare. Late relapses (i.e., recrudescences) are never seen, except possibly with varicella: it has been suggested that zoster is a recrudescence of varicella. In some of these diseases a solid lifelong immunity is the rule. Yellow fever is a good example of this. In others, smallpox included, there are sometimes second attacks after a lapse of years. The immunity to sheep-pox, fowl-pox, and contagious ecthyma is said to wane after a few years, but, since the natural host has only a short life, second attacks are not commonly seen. It is, however, characteristic of a first-class immunity that at least for a few years it is solid: second attacks do not occur either naturally or after experimental inoculation.

A significant feature of class-I diseases is that all strains of each of the viruses are antigenically similar—i.e., one cannot distinguish by serological means between strains of virus isolated from different outbreaks of the same disease. (I am regarding the various forms of arthropod-borne encephalitis as distinct diseases.)

All class-I diseases on recovery give rise to antibodies which neutralise the virus—i.e., antibodies in the presence of which the virus cannot infect cells. These antibodies usually persist in the circulation for long periods, commonly for years. Most of these diseases are systemic diseases in which the virus spreads in the blood-stream so as to reach the tissues where the characteristic lesions develop. Thus one would expect immunity to be effective so long as there was any neutralising antibody in the circulation.

A further factor operating in the acute exanthems of man and in mumps, and in some of the other diseases in this group, is that the primary infection takes place in the respiratory tract, and is followed by a long incubation period. This long incubation period would give time for a person with a basic immunity to respond with a rise in antibody before the virus had spread throughout the body. In some of these diseases perhaps what appears to be a permanent solid immunity is only an immunity to the fully developed disease, and repeated unapparent infections of the respiratory tract may take place. Unapparent infections can occur in partly immune animals. On the other hand, we know that, with yellow fever and measles for example, a solid immunity is maintained indefinitely in the absence of further contact with the virus.

TABLE I

Class I	*Class II*
Smallpox	Influenza
Varicella	Poliomyelitis
Measles	Dengue
Rubella	Foot-and-mouth disease
Sheep-pox	African horse-sickness
Fowl-pox	Blue-tongue of sheep and cattle
Contagious ecthyma of sheep	African swine-fever
Mumps	
Canine distemper	
Swine fever	
Cattle plague	
Panleucopenia of cats	
Equine "*influenza*"	
Fowl plague	*Class III*
Newcastle disease	Psittacosis
Infectious laryngotracheitis	Lymphogranuloma
Infectious bronchitis	Trachoma
Yellow fever	Equine infectious anæmia
Rift valley fever	Virus pneumonia of swine
Arthropod-borne encephalitis	Grey-lung disease of mice

VIRUSES PRODUCING A SECOND-CLASS IMMUNITY

Class-II diseases, like those in class I, run a rapid course usually followed by elimination of the virus, except for the very occasional carrier animal. Relapses and recrudescences are unusual. The special feature of these diseases is that second attacks may occur at any time and their severity may be quite uninfluenced by the previous infection. The main reason for this lack of protection is that all these viruses have a variety of antigenic types and/or subtypes. Thus there may be little or no cross-immunity between different strains of the same virus. This has a serological basis in that although all these diseases give rise to neutralising antibodies to the strains of virus causing the attack there is little or no cross-neutralisation between different types, and even subtypes show only partial cross-neutralisation.

---

[*] Almroth Wright lecture delivered at St. Mary's Hospital Medical School, on May 13, 1952.

Some at least of these viruses have an interesting characteristic, which is no doubt associated with the fact that each is found occurring naturally in a variety of immunological types: their antigenic character is not fixed but is continually changing. This is well seen in influenza A and one suspects the same applies to foot-and-mouth disease. Presumably a virus found occurring naturally in a variety of serological types has developed those different types through its ability to change its antigenic character; so one would expect it to be still unstable in this way. It is now generally agreed that changes of serological subtypes are continually occurring with influenza A, but there is reason to suspect that even changes from one type of influenza to another may occur. In epidemics of influenza A there are usually a few cases of influenza B and vice versa. Similarly, during the present epidemic of foot-and-mouth in Europe all three main types have been found. These types remain fixed in the laboratory, but it is conceivable that in the field there are occasional mutations from one type to another.

A further reason for the inefficiency of immunity in the case of the influenza viruses (and probably as yet undiscovered viruses of the respiratory tract) may be that the disease develops by the virus spreading over the surface of the mucous membrane without contact with the blood-stream. Similarly poliomyelitis may infect the mucosa of the alimentary canal and establish itself even for considerable periods despite the presence of antibody in the circulation.

Francis (1947) thinks that the surface nature of influenza infection is the main reason for the shortness of immunity in this disease; but I doubt whether this factor is as important as he says. Influenza B seems to confer a considerably longer immunity than does influenza A, because the former recurs in epidemic form at longer intervals than A, and in a recent epidemic in this country the age-incidence was such as to suggest that immunity lasted many years, the disease being largely confined to children. We have no direct information on the duration of immunity to influenza B, but the evidence suggests that it is many years; in fact if we were to regard influenza B as a distinct disease I should feel inclined to include it in class I. Yet influenza B is a surface infection just as much as A is. The latter, however, seems to have a greater range antigenically than B does, and it is this great variability which I regard as far the most important reason why it produces a second-class immunity. Another point in favour of this view is that the prevalent immunological subtype of influenza A seems to change in a major way every few years, suggesting that the community becomes too immune to the older subtypes for them to be able to produce epidemics.

Except possibly for these diseases which are surface infections, immunity to homologous strains of class-II diseases is probably as durable as is immunity to class-I diseases. Second infections with the same type of foot-and-mouth after rather short intervals can probably be explained as being due to differences between subtypes which have only lately been appreciated. Immunity to natural exposure with the same strain of foot-and-mouth lasts about two years. However, foot-and-mouth may be in rather a special category inasmuch as it multiplies extremely rapidly and is probably more infectious than any other known virus.

VIRUSES PRODUCING A THIRD-CLASS IMMUNITY

For the immunological characters of the first two classes, then, fairly satisfying explanations are forthcoming, although there are some points to which we shall refer again presently. Class III presents a very different picture. It includes both systemic and localised diseases, and there are acute and chronic phases. The main feature they have in common is that the infection, and often the lesions, persist for long periods. Relapses are common under adversity and may occur long after the initial infection, so might more appropriately be called recrudescences; these are often severe and even fatal.

Although in these diseases there is not an immunological mechanism capable of rapidly eradicating the virus or of preventing recrudescences under stress, the animal is usually refractory to further inoculation so long as it remains infected. Thus human beings infected with lymphogranuloma resist inoculations of active virus into the skin on a part of the body remote from the lesions. A considerable degree of immunity can be engendered in mice by intraperitoneal inoculation of live psittacosis virus. It is not quite clear how far immunity continues after viruses of the psittacosis-lymphogranuloma group have entirely disappeared from the host, but it seems that at least some degree of resistance persists. This, however, is not so with grey lung or trachoma, or with equine infectious anæmia. If these infections are cleared up, for instance by chemotherapy, the host becomes fully susceptible to reinfection. Repeated inoculations of active grey-lung virus intraperitoneally confers no immunity to intranasal inoculation.

Viruses of the psittacosis group are not neutralised to any significant degree by the sera of convalescent people or animals. It is possible sometimes to demonstrate neutralisation, especially with hyper-immune serum prepared in fowls, but this is of a low order compared with what can be demonstrated with viruses in classes I and II. Similarly, neutralisation by antisera is either absent or feeble with trachoma, virus pneumonia of pigs, and grey lung of mice. With infectious anæmia of horses the virus can be isolated from the blood for long periods; so apparently there is no neutralisation of this virus either.

The common factor in class-III diseases then seems to be lack of any significant degree of neutralisation by antiserum. Several of them are systemic infections and may have an acute febrile phase; so there is nothing about their character that might explain why neutralising antibodies are not formed; indeed we know that complement-fixing antibodies are formed in some of them. Therefore we must regard lack of neutralisation, or weak neutralisation, as a property of the virus and not as due to any character of the disease such as lack of sufficient antigenic stimulus.

One wonders whether the weak neutralisation that can sometimes be shown with the psittacosis group is not more analogous to sensitisation of bacteria with antiserum than to neutralisation as seen with viruses of class I and II—i.e., preparation for phagocytosis rather than prevention of infection of cells. Antiserum affects bacteria in several ways, perhaps the most important of which is to render the bacteria more liable to phagocytosis. Antibodies have similar actions on viruses, but in addition certain antibodies—the neutralising antibodies—are able to prevent the virus infecting the susceptible cell. With some viruses, those of the influenza group for example, the elementary body is prevented from attaching itself to the cell, while in vaccinia the elementary body can attach itself to the cell but antibody seems to interrupt its progress at this stage. This is what I mean by true virus neutralisation.

This lack of neutralisability of class-III viruses may imply that with them the virus-cell relationship is basically different from that with other viruses. A fundamental difference is also suggested by the fact that several of them—psittacosis, lymphogranuloma and other members of this group, trachoma, grey lung, pneumonia of pigs—are susceptible to certain antibiotics. It has been suggested that some of these agents may have a phase of multiplication outside the cell, and indeed microscopic studies have been made which lend support to this view, at least so far as the psittacosis-lymphogranuloma group is concerned (Weiss 1949). It is significant also that all viruses of class III are large, perhaps with the exception of equine infectious anæmia which on not very substantial experimental evidence is said to be not more than 50 µ in diameter. Thus in several respects these viruses occupy a position between the bacteria and more typical viruses, infectious anæmia perhaps being an exception owing to its suspected small size.

SOME ANOMALIES

When we try to arrange biological material into an arbitrary scheme of classification it is often salutary to look at the exceptions that do not fit.

Herpes appears at first sight to belong to class III, since the virus persists and relapses are common. However, there is no persistence of lesions and the relapses are minor and localised—not so serious as the original infection, as the relapses with the other members of class III are. With herpes there is neutralisation with antibody and it has only one serological type. Thus herpes is best regarded as an atypical class-I virus.

Two other odd diseases are lymphocytic choriomeningitis and St. Louis encephalitis infections of mice. There are two anomalies here: (*a*) the viruses often persist even though they are susceptible to being neutralised by antibodies, which however appear very late, and (*b*) recovered mice are immune in the absence of neutralising antibodies—i.e., before they are formed. For some reason that we do not know, neutralising antibodies to lymphocytic choriomeningitis are not formed in any animal for at least several weeks, and in mice, especially those which have become infected in utero, neutralising antibodies may never be formed and the virus may persist in the circulation for many months. These two diseases have been cited by some writers to support the view that neutralising antibody is not the main factor in immunity to viruses. We shall return to this point later. These two viruses must be regarded as intermediates between class I and class III.

The tumour-causing viruses, for instance the Shope papilloma and Rous sarcoma, are known to be susceptible to neutralisation by antibody; yet the tumours persist for a considerable time. The probable explanation is that, as the tumour cells divide, the virus passes to the daughter cells and so need not come in contact with antibody. Most other viruses cause cells to rupture; indeed they have to do so in order to escape and spread to other cells. They risk coming in contact with antibody before getting into the next cell, whereas the tumour viruses stimulate the cells to multiply and do not cause them to rupture. It is well known that all viruses are out of the reach of antibody while they are inside cells.

Some difficulties also arise in trying to fit into this scheme those diseases which have incubation periods running into months—namely, rabies, infectious hepatitis of man, serum hepatitis, and scrapie of sheep. I think rabies would fit satisfactorily into class I but we have not enough data about the other three viruses to attempt a classification.

These anomalies do not invalidate the proposed system of classification because it is common experience in biology to meet intermediates.

CONCLUSIONS FROM THE FOREGOING

In summary, then, the different classes of immunity are not to be explained by the characters of the diseases but by the characters of the viruses. The significant factor seems to be neutralisation of the virus by antibody. The general principle we have been looking for to explain the different classes of immunity may be stated as follows:

> Class-I viruses are neutralisable and each disease has only one antigenic type of virus.
>
> Class-II viruses are neutralisable but have a multiplicity of antigenic types and these may be subject to continual change.
>
> Class-III viruses are not susceptible to neutralisation in the way the others are.

Conversely, if a virus is neutralised by its antiserum and there is no persistence of lesions one can expect a first-class or second-class immunity; but if there is no neutralisation and lesions persist one can expect only a third-class immunity.

Thus in a general way the class of virus immunity can be explained in terms of neutralisation by antisera, and taking a superficial view one might be tempted to end this review here. This, however, is not the whole story. On the one hand, as we have seen, there may be resistance without neutralising antibodies in the class-III diseases and in lymphocytic choriomeningitis and St. Louis in mice. On the other hand the presence of neutralising antibody does not always confer immunity—against influenza or lymphocytic choriomeningitis, for instance.

ARTIFICIAL IMMUNISATION

Let us see if we can get more light on the underlying principles of virus immunity by examining information about artificial immunisation. A glance over the various vaccines available will also serve as an introduction for some ideas I am going to put forward about possible new developments in virus vaccines.

Active Immunity

Active immunity may be produced artificially by inoculation of relatively large amounts of killed virus or inoculation of a small amount of living virus sufficient to set up infection.

Living virus is still used in the fully virulent state for immunisation against some animal diseases. It is either inoculated by an unnatural route or given under cover of antiserum. Usually an immunity follows which is equal to that after a natural attack; but the use of virulent virus has obvious disadvantages, and the most popular and successful methods of vaccination are those employing attenuated strains. Attenuated vaccines are now used against smallpox, fowl-pox, distemper, swine fever, cattle plague, fowl plague, Newcastle disease, yellow fever, Rift valley fever, dengue, African horse-sickness, blue-tongue, and rabies. These attenuated strains set up a mild or an unapparent infection which confers an immunity which is usually not greatly inferior to that following a natural attack. It may be noted in passing that it is not always easy to produce just the right degree of attenuation. There is not only the danger of insufficient attenuation; the process can be carried too far, so that the virus fails to produce immunity.

Killed vaccines against virus diseases are of comparatively recent introduction. It used to be believed that immunity to virus could be produced only by living virus. This was a misconception which originated from our inability to produce virus antigens in sufficient quantity free from excessive amounts of other protein.

Killed vaccines are now available against the following diseases: swine fever, cattle plague, Newcastle disease of fowls, feline panleucopenia and certain forms of arthropod-borne encephalitis, influenza A and B, foot-and-mouth disease, rabies, and abortion of ewes. These vaccines give rise to neutralising antibodies, but the immunity they confer lasts not more than six to twelve months, even though the disease is one in which a first-class immunity follows a natural attack. However, in some diseases, like mumps, a basal immunity may be all that is needed to raise the percentage of unapparent infections from the usual 50 to nearly 100. This is most likely to be achieved in those diseases which have a long incubation period and which normally give rise to a high proportion of unapparent infections. This field has not been explored.

Looking at the data on artificial immunity in the light of our classification we see that, as one would expect, it is against diseases in *class I* that most of the successful vaccines have been prepared. The best of these are attenuated living vaccines, but useful immunity lasting up to a year has been produced by some killed vaccines. In *class II*, whether living or killed vaccines are used, the problem is to include in the vaccine strains producing an immunity to those strains likely to be encountered. This involves constantly examining the antigenic character of the wild strains and adding any new types or major subtypes to the vaccine. *Class-III* diseases would seem, a priori, the most difficult to vaccinate against successfully, and this is what we find. Immunity has been obtained experimentally against psittacosis and lymphogranuloma by repeated inoculation of living virus intramuscularly or intraperitoneally. Killed vaccines against these two agents confer some resistance (Wagner et al. 1946), but it is generally agreed that this is of a low order, and the same applies to feline pneumonitis. Recent reports indicate that satisfactory immunity against the natural disease can be obtained in ewe abortion (a member of psittacosis group) with formalised vaccines (McEwen et al. 1951).

Passive Immunisation

Effective temporary immunity can be conferred against several virus diseases by administration of antisera. It is probably correct to say that this applies to all the diseases in classes I and II provided suitably potent and specific sera are available. Probably no protection against class-III diseases is conferred by antisera.

Summary

Thus the results of artificial immunisation are in general what one would expect from a knowledge of natural immunity. Two points, however, emerge. Firstly, the efficacy of passive immunity provides convincing evidence of the important rôle of humoral factors in immunity to viruses in classes I and II. Secondly all killed vaccines so far put into use produce at best an immunity that is short-lived and inferior to that produced by living vaccines or a natural attack, even though they may produce reasonably good levels of neutralising antibody.

THEORY OF VIRUS IMMUNITY

Any general theory on the mechanisms of immunity to viruses must take into account the following points, among others: (*a*) infection with the virus confers a better immunity than does vaccination with killed virus; (*b*) although immunity and neutralising antibody generally run parallel, with some diseases immunity may be present in the absence of neutralising antibody, and vice versa.

The first point is accounted for by some people by hypothesising that those viruses which confer a long-lasting immunity persist almost indefinitely in the host, even though there is no evidence of their presence: thus there is a continual antigenic stimulus or, alternatively, the presence of the virus may prevent further infection by means of the interference phenomenon. While we know that some viruses do persist for long periods, there is no direct evidence that this is so with most of the class-I diseases. For this reason, and because there is no way of testing the hypothesis, it seems to me more reasonable to look for some other explanation.

The second point, lack of correlation between neutralising antibody and immunity in certain diseases, has led some virus workers to conclude that the principal factor in immunity to viruses is specific cellular immunity and not antibody. However, attempts to demonstrate cellular immunity by tissue culture or grafting experiments have failed; and, indeed, it is difficult to imagine the mechanism of such an immunity, unless possibly it is either in the nature of an interference phenomenon or is due to antibodies attached to the cells; but I doubt if either of these mechanisms is what those who favour cellular immunity have in mind.

It seems to me that we may be able to dispense with the rather obscure concept of specific cellular immunity and with the idea of viruses persisting without being demonstrable. In all these diseases antibodies are produced even if they do not neutralise; a basic immunity is set up—i.e., the ability to produce antibody very rapidly and in high titre on second contact with the virus—and a specific allergy to the virus is produced. It is reasonable to assume that these three factors operate in immunity to all virus diseases, but in addition there is neutralisation in the class-I and class-II diseases, and this, when present, is of overriding importance.

Allergy is usually left out of discussions on immunity to viruses, although it was remarked on by Edward Jenner who first reported that an infection with a virus results in a subsequent heightened reactivity to that virus. He wrote: “It is remarkable that variolous matter, when the system is disposed to reject it, should incite inflammation more speedily than when it produces smallpox.”

By inoculation of killed virus into the skin, allergic reactivity can be shown to be present in persons or animals recovered from, or chronically infected with, vaccinia, lymphogranuloma, psittacosis, trachoma, herpes, mumps, influenza, swine fever, and contagious ecthyma of sheep. The reaction at the site of inoculation reaches a maximum at twenty-four to seventy-two hours. Allergy to the infective agent is seen after recovery in all types of infectious diseases and would probably be found with all virus diseases if looked for. It seems to me most unlikely that such a general phenomenon does not serve a purpose—i.e., has not some survival value for the host.

Although there has for many years been great controversy as to whether allergy in tuberculosis and other bacterial infections is beneficial or harmful, allergy has not attracted much interest from virologists, except as a method of indicating past or present infection. I believe the rôle of specific allergy is to activate and enhance the effectiveness of humoral and cellular defences—i.e., to mobilise the defences at the site of invasion. Thus the three factors—antibody, cellular reaction, and allergy—should be regarded as interdependent and operating together. The outcome of initial infection must be considerably influenced by the vigour of the local reaction to it and also by the speed with which the reaction develops. Speed is perhaps even more important in virus than in bacterial infections because the antibody cannot exert its effect after the virus gets inside the cells.

Thus it seems highly probable that allergy helps the body resist invasion of the epithelial surfaces. Whether or not it is beneficial after the infection has already become established in some internal organ is a different question and may depend on the extent of the infection.

When vaccinia is reinoculated into animals or people who have recently had a previous infection with the virus, there is a rapid and vigorous reaction at the site of inoculation and the infection does not become established. People revaccinated after many years often show a similar “immediate” reaction. Such reactions are apparently due to a persisting allergy to the virus, which, however, may not be associated with the continued presence of neutralising antibody. Repeated reinoculation in such persons produces in a proportion of them a full “primary”-type take. Evidently the allergic barrier, not backed up by antibody, presents a protection which is effective only in a proportion of inoculations, and once the barrier is passed there is nothing to stop a full infection developing.

I think that allergy plays a similar part in immunity to influenza. It is a reasonable assumption that allergic reactivity enables a person to react more rapidly than otherwise to infection with influenza virus and that part of this reaction consists in an outpouring of serum on to the surface of the mucosa. Such a rapid liberation of serum may prevent extensive surface spread of the virus if the serum contains appropriate antibodies. It is well known that with influenza the titre of the antibody is only roughly correlated to resistance to the disease. It may be that resistance is determined by a combination of circulating antibody and specific allergy.

Some years ago Sir Macfarlane Burnet and I produced evidence that an attack of influenza makes a person allergic to the virus (Beveridge and Burnet 1944). The evidence consisted mostly in showing a positive correlation between skin reactions and past contact with the virus as indicated by the presence of antibody, but we also reported some incidental observations suggesting that allergic symptoms may sometimes be elicited by spraying virus up the nose.

Recently indirect evidence supporting the hypothesis that allergy plays an important part in defence has come from quite a different quarter.

PATHOTOPIC POTENTIATION

Fazekas de St. Groth (1951) has found that mice immunised against influenza by intranasal inoculation are much more effectively protected against challenge inoculation than are mice inoculated intraperitoneally, and that this better protection is due to there being more antibody free on the surface of the mucosa in the mice inoculated by the intranasal route. He has further shown that this antibody on the surface of the respiratory tract, and the better protection it affords, is not due to it being formed locally in the respiratory tract, as might be expected, but is accounted for by a phenomenon he calls "pathotopic potentiation." This means that a mild inflammation set up in the respiratory tract by any agent —not necessarily a virus—results in liberation of any antibody present in the serum on to the surface of the mucosa. Thus he was able to show that mice in which antibody had been produced by intraperitoneal inoculation had their resistance greatly enhanced by inoculating into the respiratory tract chemicals causing a mild inflammation. In all such experiments he showed that the effect of the potentiating agent was to liberate antibodies on to the surface of the respiratory tract.

Friedemann (1947) and Fazekas de St. Groth have both stressed the point that as a general principle in immunity it is important for antibody to be present at the site of infection, not merely in the circulation, and they have produced a considerable amount of evidence in support of this view.

What interests me particularly about these findings is that they fit in so well with my views about the rôle of allergy. What better potentiating agent could there be than allergy specific to the infective agent? Specific allergy would seem to be Nature's means of hastening liberation of antibody on mucous surfaces or into intercellular spaces of the skin when an invasion threatens.

EXPERIMENTAL PRODUCTION OF VIRUS ALLERGY

I have carried out some experiments to find whether allergy to influenza could be produced by administration of living or killed vaccines. One group of medical students was inoculated subcutaneously with formalinised virus and another group had attenuated living virus sprayed up the nose.

The living vaccine consisted of a mixture of influenza A and B viruses which had been attenuated by repeated passage in eggs, and it was administered in the form of infected allantoic fluid sprayed up the nose with an ordinary "atomiser." The killed vaccine consisted of formalinised allantoic fluid infected with the same viruses. 1·0 ml. of each strain was inoculated subcutaneously. Skin tests were carried out at the time of inoculation and three weeks later, using a 1 in 5 dilution of virus as allantoic fluid infected with either influenza A or B or, as a control, with the virus of Newcastle disease. 0·1 ml. was inoculated intradermally in the forearm. In reactive persons an area of erythema 5–20 mm. in diameter was produced, reaching its peak in twenty-four to thirty hours. The erythema was often accompanied by slight swelling and sometimes by itching.

TABLE II—INCREASE IN SKIN SENSITIVITY TO INFLUENZA VIRUS AFTER INTRANASAL INOCULATION

Subject	Before			After			Difference

A = influenza A. B = influenza B. C = Control. The figures represent the diameter of the reactions in man

Table II shows a few selected results in people who received living virus intranasally. These results are by no means a representative sample, but I have chosen them as illustrating what happens in a proportion of cases.

Table III is a summary of the results with both methods of inoculation. It will be seen that after intranasal inoculation about half the subjects showed an increased sensitivity to each virus, whereas after subcutaneous inoculation there were very few increases. These latter probably represent only normal or chance variations, because about the same proportion of controls also showed an increase.

These results, which have been subjected to statistical analysis, show that killed vaccine in the form of formalinised allantoic fluid does not produce specific allergy, but that spraying living virus up the nose does so in a proportion of cases. I have no controls to exclude the possibility that spraying killed virus up the nose may not also produce allergy, but I think this is unlikely. Antibody titrations were not carried out on these subjects, but we know from past experience with these viruses that they produce an antibody rise in about half of the people sprayed.

THE OUTLOOK

I shall conclude with some speculation on possible future developments in vaccination against virus diseases.

It is now some eight years since Friedewald (1944) showed that killed influenza vaccines inoculated in a water-in-oil emulsion gave an extraordinarily good production of antibody which may be even higher and more sustained than that following infection with the virus. This finding has been amply confirmed, and now that Salk et al. (1951) have overcome the difficulty of finding an effective adjuvant that does not produce an undesirable local reaction it is probable that this type of vaccine will come into wide use for combating virus

TABLE III—INCREASE IN SKIN SENSITIVITY TO INFLUENZA VIRUS

Inoculation	Influenza A	Influenza B	Control
Living virus intranasally . .	23/35	15/29	4/35
Formalinised virus subcutaneously	4/27	4/17	3/27

Numerators = no. showing increase of 0·5 cm. in cutaneous reaction. Denominators = no. of subjects treated.

diseases and supersede other types of killed virus vaccines.

Ten years ago Freund and McDermott (1942) showed that allergy to horse-serum can be produced by inoculating it incorporated in a water-in-oil emulsion along with dead mycobacteria. The sensitisation was such that intradermal inoculation of horse-serum produced a tuberculin type of allergic reaction and this sensitivity lasted at least a year in guineapigs. As far as their investigation went, the presence of dead mycobacteria in the vaccine seemed to be necessary in order to produce the allergic state; therefore probably Friedewald's or Salk's vaccines do not produce allergy. Possibly a more acceptable adjuvant than mycobacteria could be found that would have this effect, and it seems likely that adjuvant, killed virus vaccines could be devised that would produce not only very high and prolonged antibody response but also a specific allergy to the virus. Such a vaccine might well produce just as good an immunity as a living vaccine. Indeed it would have one advantage over a living vaccine in that one could give a recall dose as soon as immunity waned to below a safe level, whereas with living vaccine it is not possible to revaccinate until the person has become susceptible again to the attenuated virus. Perhaps we will eventually be able even to improve on Nature and produce a better immunity than that following a natural attack of the disease.

In suggesting the development of allergenic vaccines against viruses I am assuming firstly that allergy will help in resisting invasion of the epithelial surfaces, and secondly that allergy will not be harmful in those individuals who develop the disease despite vaccination. Many pathologists would contest the second point even if they concede the first. Obviously this is a matter on which we require further information, but at present I see little reason for apprehension about the possible harmful effect of making a person allergic to a virus. If allergy were harmful one would expect to find second attacks of a disease often more severe than first attacks. Generally the opposite is the case, although there are probably exceptions to this rule. After all, the attenuated vaccines we use today produce allergy to the virus. However, a cautious approach is indicated and perhaps we should try allergenic vaccines first in veterinary work.

In a lecture of this sort some indulgence is usually granted in allowing speculation, and I have taken advantage of this. We all know, however, how unreliable even apparently reasonable speculation can be in the field of research.

"... the public should realise that they have to play their part. If they want hygienic food handling, they should not be afraid of asking for it and of commenting when they see hygienic failures. How many restaurant customers have the moral courage to send back to the kitchen a cup or fork which is placed before them dirty? How many just wipe it on the tablecloth and say nothing? And the spending of a few minutes behind the counter of a snack bar shows forcibly how the public cough or sneeze germs over the food on display or tentatively touch it with fingers far dirtier than any employee would dare to have."—Dr. J. D. KERSHAW, medical officer of health for Colchester, in his annual report for 1951.

EXACT DETERMINATION OF THE CENTRAL VENOUS PRESSURE

BY A SIMPLE CLINICAL METHOD

J. G. G. BORST M.D.
J. A. MOLHUYSEN Arts

From the Department of Medicine, University of Amsterdam

THE central venous pressure is the pressure in the veins close to the right atrium of the heart: it is virtually the same as the pressure in the right atrium when this part of the heart is in diastole.

The central venous pressure depends on the quantity of blood returned to the heart in a given time (venous return) and on the ability of the heart to pump it out (competence). There is a reciprocal relation between the central venous pressure and the function of the heart.

The pressure in the atrium can be measured in relation to the atmospheric pressure (actual pressure) or to the intrathoracic pressure round the heart (effective pressure). The effective venous filling pressure is the algebraic difference between the actual pressure and the intrathoracic pressure (Henderson and Barringer 1913, Wiggers 1914).

In the heart-lung preparation the venous pressure regulates the cardiac output (Patterson and Starling 1914, Wiggers and Katz 1922). In the intact healthy body, on the other hand, hormonal and nervous factors exercise a great and sometimes overwhelming influence. When the heart becomes insufficient it behaves more like the heart-lung preparation of Starling, and the dependence of the cardiac output on the venous pressure is then seen quite clearly (Richards 1947). Although it would be more accurate always to measure the effective venous pressure, one must in practice be satisfied with the measurement of the actual pressure.

CLINICAL SIGNIFICANCE OF CENTRAL VENOUS PRESSURE

(1) *A single determination* of the central venous pressure tells us whether the right heart is efficient or not (either at rest or after exertion), and thus whether œdema and ascites are of cardiac, extracardiac, or mixed origin. It can also tell us whether an acute state of shock has a central origin (cardiac infarction or lung embolus) or is due to a decrease in the blood volume or to peripheral vasodilatation. Further, it is a valuable aid in the differential diagnosis of dyspnœa: in the presence of left cardiac insufficiency, with pulmonary congestion, the venous pressure is almost always raised; but, when the dyspnœa is pulmonary in origin, especially in asthma, emphysema, and chronic bronchitis, the venous pressure (during inspiration) tends to be strikingly low, provided there is no concomitant appreciable damage of the right heart.

(2) *Repeated determinations* of the central venous pressure over a period are an excellent measure of spontaneous changes in the state of the heart in cardiac patients and of the effect of rest in bed, salt-free diet, diuretics, digitalis, quinidine, and other therapeutic agents. An increase in venous pressure during intravenous infusion gives warning of overloading of the heart. The influence of the retention of water and sodium chloride on the circulation may easily be determined by following changes in the venous pressure in renal diseases (especially acute glomerulonephritis) and during treatment with adrenal cortical hormones or related compounds.

Any scientific investigation into the control of the circulation is incomplete if the changes in the venous pressure are not followed in detail.

PREVIOUS METHODS OF MEASUREMENT

The method to be used to measure the venous pressure in the above-mentioned types of cases should not be unpleasant for the patient, and the determination should not take too much time. The results obtained by experienced investigators must be accurate to at least 1 cm. of water; for an increase in the diastolic pressure in the right ventricle by 2·5 cm. of water may cause in normal people a rise of 40% in the cardiac output (Cournand et al. 1948). The methods in use hitherto have not fulfilled all these requirements, and this is why the measurement of the venous pressure has not become universal in routine clinical examination or scientific investigation.

Method of Moritz and von Tabora

For measuring the peripheral venous pressure a large needle is inserted into the cubital vein and connected to a manometer filled with sterile sodium citrate (Moritz and von Tabora 1910). The results obtained in normal people by numerous observers have varied very greatly and are 4–12 cm. of water higher than the pressure in the right atrium. The values obtained by the method of Moritz and von Tabora in cases of congestive heart-failure are sometimes improbably high. This is due to the distance between the atrium and the point at which the pressure is determined. As a result the speed of the blood flowing in the vein, and the diameter of the lumen of the vein, which may change by vasoconstriction or dilatation, exert a considerable influence on the value found. The supposition that there is always a linear relation between the peripheral venous pressure and the right atrial pressure cannot be upheld, as has been shown by Moia et al. (1950) and Pedersen (1952). If the vein collapses anywhere between the point where the pressure is determined and the right atrium, the linear relation fails immediately (Ryder et al. 1944). Negative pressures cannot be measured in the peripheral veins (Doupe et al. 1938).

Since the introduction of cardiac catheterisation into clinical methods (Forssmann 1929, Cournand and Ranges 1941, McMichael and Sharpey-Shafer 1944a) it has been possible to determine the mean pressure in the right atrium with a manometer attached to the cardiac catheter. It is clear, however, that this is impracticable as a routine method and especially as a method of following changes in the venous pressure over long periods.

Method of Lewis

Lewis (1930) laid the foundation for the determination of the central venous pressure by using the external jugular vein as a manometer to record pressure changes in the right atrium. He stated that in normal persons the zero (or atmospheric) pressure level of the fluid in the venous system is near the attachment of the second rib to the sternum at the angle of Louis. This would apply for any position of the body, lying, sitting, or standing. Although Lewis used the method of Moritz and von Tabora for *measuring* the venous pressure, he stated:

> "If therefore we can gauge the precise level at which the veins collapse we have a gauge of the filling of the venous reservoir, or to be more exact of right auricular pressure."

McMichael (1938) obtained as good results by Lewis's method as by that of Moritz and von Tabora. We are of the opinion that of the two methods that of Lewis is much to be preferred, provided that the technique is modified and standardised. The distance between the point where the pressure is recorded in the external jugular vein and the right atrium is short, and the lumen of the vein is large; hence pulsations caused by the contraction of the heart and by respiration are little altered. By always making the patient lie so that the vein is partly filled it is possible to measure negative pressures. The pressure in the external jugular vein during atrial diastole is thus almost equal to, and certainly closely related to, the pressure in the right atrium.

THE MODIFIED METHOD OF LEWIS

During the past ten years, investigations have been made in our clinic to develop a standard technique for the measurement of the central venous pressure. The provisional results have already been published by Allen (1948). Like Leishman (1946) we originally used a simple measuring device, which we later modified. Whereas Leishman found the same values as Lewis in normal people, Allen, with the standardised method, obtained results 5 cm. lower than those of either of these observers, and 6–10 cm. lower than those obtained by the method of Moritz and von Tabora for peripheral venous pressure.

Since 1948 we have measured the central venous pressure in a large number of normal persons, and our results are still lower than those reported by Allen, although only slightly so. Great care must be taken to have the patient lying in a good position, and the pressure is measured only when the patient is emotionally and bodily at rest. If attention is paid to these points, the results obtained by two experienced persons generally differ by not more than 0·5 cm.

Since the end of 1947 the measurement of the central venous pressure by the modified method has formed part of the routine examination of all patients, whether admitted to the clinic or attending as outpatients. It has been an indispensable link in our investigations into the relation between the circulation and the excretion of water and electrolytes (Borst 1948, Molhuysen et al. 1950, Blomhert et al. 1951).

Principle of Method

If the external jugular vein is to be used as an atrial manometer, two requirements must be fulfilled:

(1) There must be free communication between the neck veins and the right atrium. We therefore can only measure the pressure when the valves in the veins are open—*i.e.*, during inspiration and falling atrial pressure ("negative" *x* and *y* wave or trough of the venous pulse tracing). During expiration and during atrial systole the central venous pressure rises and the valves of the veins close. *Thus during expiration and atrial systole the filling of the vein does not reflect the atrial pressure; moreover the determination of the highest point to which the vein is filled is more difficult than the determination of the lowest point of complete collapse of the vein.*

(2) There should theoretically be no flow of blood in the vein while the pressure therein is being measured. Therefore *we obstruct the peripheral blood-stream by light pressure* with the finger on the distal end of the vein just below the angle of the mandible. A new potential source of error is introduced by closing the upper end of the manometer, but *this does not prevent the obtaining of a reliable reading, since* the vein is not a rigid tube and does not require any significant pressure to cause it to collapse.

Reference Point

The pressures in the heart are measured in centimetres of water in relation to atmospheric pressure, which is regarded as nil (actual pressure). To eliminate hydrostatic factors the intracardiac pressure must be measured from a horizontal plane through the heart. This plane cannot be determined; therefore a fixed reference point is used on the thorax. The vertical distance from this point to the selected horizontal plane should be as constant as possible. Following Bloomfield et al. (1946) we chose a plane 5 cm. below the angle of Louis with the patient lying horizontal. In theory the plane should pass through the centre of the right atrium, but in practice this is often far from the case. In every person the position of the plane in relation to the reference point is different; moreover it varies with respiration and during the cardiac cycle. Bloomfield et al. measured in normal people the vertical distance from the angle of Louis to the midpoint of a straight line between the anterior tip of the ventricle and the lowest point of the atrium by lateral radiography. They found an average value of

the vein. A mark is made on the skin to indicate the lowest point of collapse, followed by the actual measurement of the pressure.

For the determination of the difference in level between the point of venous collapse and the reference point we use the instrument shown in fig. 5. A small spirit-level is incorporated in the horizontal arm. The method of use is obvious from the figure.

Although it is simple, the determination of central venous pressure, like any clinical method, has to be learnt by experience.

Difficulties in Finding Correct Point of Collapse

(1) The external jugular vein may be kinked at the thoracic inlet if the neck is flexed too far forwards, or if it is too far extended, whereby the muscles of the neck are not relaxed. It is also possible for the head to be insufficiently or excessively rotated. Occasionally no pulsations are seen while the vein is distended. By improving the position of the patient or the rotation of the head, pulsations can usually be brought into view and the vein made to collapse after interruption of the centripetal blood-stream. The vein may be kinked even if pulsations are seen, because the posterior facial vein divides into two parts, of which the posterior helps to form the external jugular vein, and the anterior helps to form the common facial vein, which joins the internal jugular vein. Blood may thus reach the atrium by the alternative path; the intermittent flow causes pulsations, but the external jugular vein will not collapse at the "lowest point." The point of collapse is then usually not sharply defined until the venous occlusion at the thoracic inlet is overcome, and a direct route established for the flow of blood from the external jugular vein to the right atrium.

Fig. 4—Jugular venous pulse and heart sounds.

(2) The measurement of the pressure may be difficult if the external jugular vein is poorly developed and pulsates poorly (in 14% of the patients in our series). In this event sometimes the internal jugular vein should be used.

(3) In severe shock the pulsations in the external jugular vein are small and the vein is contracted. It may be impossible to measure the central venous pressure in such cases.

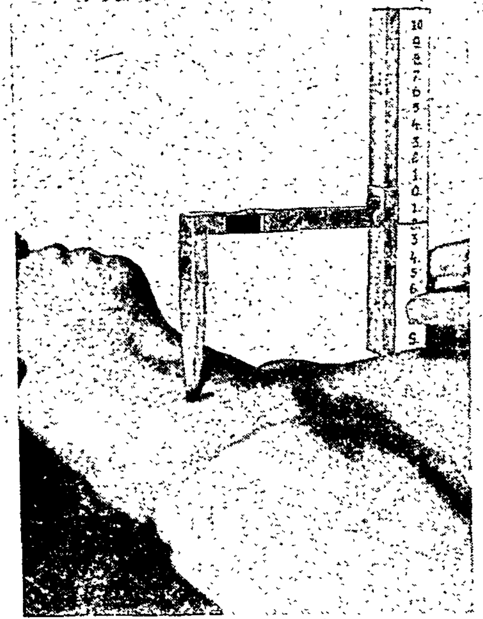

Fig. 5—Method of measuring central venous pressure. A spirit-leve is incorporated in the horizontal arm. Central venous pressure is +3 cm. of water (2 cm. below sternal angle).

(4) Sometimes there are no pulsating or collapsing veins in the neck, as a result of which it may be impossible to measure the venous pressure at all (6% of our cases).

(5) Unilateral or bilateral congested veins without pulsations, even in the sitting position, indicate obstruction to the return of venous blood to the heart, from pressure on the large veins and heart—e.g., mediastinal tumours, enlarged lymph-glands, and aortic aneurysm—or thrombosis of the veins.

RESULTS

Of a series of 400 outpatients:

1. The central venous pressure was determined without difficulty in 321 (80%). The external jugular veins were well developed, pulsated well, and collapsed clearly.
2. The pressure was determined less easily or with difficulty in 55 patients (14%). The external jugular veins were less well developed, pulsated less actively, or collapsed less clearly, and in some cases pressure had to be measured in the internal jugular vein.
3. The pressure could not be measured in 24 patients (6%). There were no visible neck veins or it was impossible, in spite of every attention to the position of the patient, to find a vein which pulsated or collapsed well.

In 332 cases two experienced observers determined the central venous pressure independently. The results showed no difference in 195 (59%); a difference of not more than 0·5 cm. in 104 (31%); and a difference greater than 0·5 cm. in 33 (10%). Thus in 90% of the

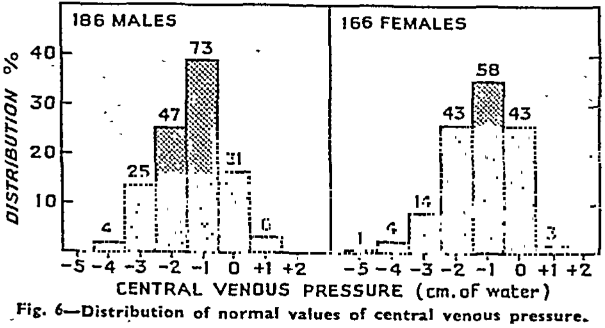

Fig. 6—Distribution of normal values of central venous pressure.

cases investigated the duplicated determinations differed by not more than 0·5 cm.

NORMAL CENTRAL VENOUS PRESSURE

We have taken as normal the results obtained in 352 completely investigated outpatients (186 males and 166 females) who showed no abnormality of the circulatory or respiratory systems, and in whom no definite anæmia or decrease in the plasma-proteins was demonstrable.

Since the error in measurements is generally not more than 0·5 cm., the results are grouped at intervals of 1 cm.: from +1·5 to +0·5 cm., from +0·5 to −0·5 cm., from −0·5 to −1·5 cm.,...from −4·5 to −5·5 cm. The distribution of the normal figures for these males and females is given in fig. 6, which shows that the greatest frequency is found in the interval from −0·5 to −1·5 cm. in both sexes.

The result of the calculation of onesided confidence intervals for the percentages of males and females with a central venous pressure between +0·5 and −3·5 cm. of water is as follows: with a confidence coefficient of 0·005 (0·5%) at least 88% of the males have a central venous pressure between +0·5 and −3·5 cm. of water, whereas with a confidence coefficient of 0·1 (10%) at least 91% lie between +0·5 and −3·5 cm. of water. For the females these figures are 89% and 92% respectively.

In a series of 165 men and 145 women not only was the central venous pressure and the age known, but also the diameter of the thorax at the level of the angle of Louis. The relations between the central venous pressure on the one hand, and the age and the thoracic diameter on the other were statistically investigated. There was found to be a definite relation. To eliminate this factor of dependency of the central venous pressure on age and diameter of the thorax a correction table was compiled from our observations (Molhuysen 1952). New histograms were constructed, but these did not differ materially from the original histograms, and we have given up using them.

Daily Variation

The changes in central venous pressure during the day are fairly large, but seldom more than 1 cm. in normal persons. Patients with a raised central venous pressure often show changes of several centimetres.

RELATION BETWEEN CENTRAL VENOUS PRESSURE AND MEAN PRESSURE IN RIGHT ATRIUM IN NORMAL PERSONS

Several investigators have measured the mean pressure in the right atrium with a manometer attached to a cardiac catheter, with the subjects lying down. In table I we compared their results with the normal values for the central venous pressure determined by our method.

McMichael and Sharpey-Shafer (1944b) took the horizontal plane through the angle of Louis as their zero pressure level. Their figure is therefore increased by 5 cm. to make it comparable with those of other investigators, who, like ourselves, used a horizontal plane 5 cm. below the angle of Louis as zero pressure level.

Because in our method the pressure in the jugular vein is determined when the pressure in the atrium is lowest—i.e., during inspiration and ventricular systole—it is to be expected that our results will be lower than the mean pressure in the atrium. The pressure in the right atrium changes during the cardiac cycle by about 3–4 mm. of mercury (Cournand et al. 1951). Our results, which are slightly lower than those of Allen (1948), agree satisfactorily with those of Bloomfield et al. (1946), account being taken of the above factors.

TABLE II—CENTRAL VENOUS PRESSURE AND MEAN RIGHT ATRIAL PRESSURE MEASURED SIMULTANEOUSLY

12	F	20	Patent ductus arteriosus	8	0	−1

SIMULTANEOUS MEASUREMENT OF CENTRAL VENOUS PRESSURE AND MEAN PRESSURE IN RIGHT ATRIUM

In 11 cases of congenital heart-disease and 1 of mitral stenosis we measured the central venous pressure with the patient lying down and at the same time the mean pressure in the right atrium by connecting an intracardiac catheter to a water manometer. The results are given in table II.

Except for 1 patient the pressure in the jugular vein was equal to, or less than, the pressure in the atrium. In 8 cases the difference was 1 cm. or less, in 2 cases 1·5 cm., and in 2 cases 4 and 4·5 cm. One of these latter showed a raised mean pressure in the right ventricle. We could not ascertain whether the systolic pressure in the right atrium was higher than normal in the last 2 cases. In general there was very good agreement between the central venous pressure and the mean right atrial pressure.

FACTORS INFLUENCING CENTRAL VENOUS PRESSURE

In discussing several factors which may exert an influence on the central venous pressure one must distinguish patients with normal cardiac function from those with cardiac insufficiency.

Respiration

During normal respiration the changes resulting from changes in the depth of inspiration are less than 0·5 cm. Although we observed differences of 0·5–2·0 cm. between the pressure measured during inspiration and that measured during expiration, it is questionable, as already stated, whether the pressure during expiration can be measured by our method, since the valves will close immediately, when there is a reversal of direction of blood-flow. This is not a serious objection to the method. If the respiration is normal, the mean difference between the minimum pressure in the right atrium during inspiration and the minimum pressure during expiration is not

TABLE I—NORMAL VALUES OF CENTRAL VENOUS PRESSURE AND MEAN ATRIAL PRESSURE

more than 1·6 cm. of water; though an extreme value of 2·4 cm. of water has been found (Battro et al. 1949).

During forced inspiration the central venous pressure falls several centimetres. The values obtained with our method will then be much lower than those of the mean right atrial pressure. This is seen sometimes in patients with emphysema, bronchial asthma, or chronic bronchitis. If there is severe dyspnœa it is impossible to measure the pressure, because the veins are sucked completely empty in whatever position the patient is placed.

Although the pressure in the atrium falls during inspiration, this change is partly compensated for by the more rapid return of blood to the heart. The effective pressure in the right atrium increases in inspiration and falls in expiration (Lauson et al. 1946).

Posture

So long as the jugular vein collapses between the angle of the mandible and the clavicle, it is possible to determine the central venous pressure by our method. If the central venous pressure is measured first with the patient horizontal, and the body is then elevated to 30° from the horizontal, small changes will be found, usually not more than 0·25–0·50 cm. and never more than 1 cm. (Allen 1948). When the central venous pressure is raised, the patient will have to be more or less sitting, whereby the vertical distance from the centre of the atrium to the reference point alters and the result will differ from that which would be obtained with the patient lying down. When the central venous pressure is much raised, the change in position of the heart will exert relatively little influence on the result. The venous return falls slightly with the patient sitting, and the pressure is found to be slightly lower than with the patient lying down. The reverse obtains for the Trendelenburg position.

Exertion

In 376 outpatients with a normal circulatory system the central venous pressure did not rise after twenty "knees-bends" but remained constant or fell by at the most 0·5 cm. This fall may be explained by the deeper inspiration.

In cardiac patients with a raised central venous pressure a rise of several centimetres was seen after exertion (drawing up of the legs) followed by a slow return during 1–5 minutes to the original level. If the central venous pressure is normal in a patient at rest, one can discover by the effect of exertion whether there is latent cardiac insufficiency.

Pressure on Liver: Hepatojugular Reflux

In the same group of 376 patients with normal cardiac function no rise of the central venous pressure was seen during pressure on the region of the liver, if the patients continued to breathe quietly.

In the presence of latent or manifest cardiac insufficiency the central venous pressure rose several centimetres. Cessation of the pressure was followed by a rapid return of the venous pressure to the initial value. We apply this test in conjunction with the exertion test to diagnose latent cardiac insufficiency.

Emotion

In patients with normal cardiac function no measurable change in central venous pressure due to emotion was observed. In the presence of impaired cardiac function and a raised central venous pressure we often observed a further rise of several centimetres under the influence of emotion.

SUMMARY AND CONCLUSIONS

By a modification of the method of Lewis it is possible to measure the central venous pressure rapidly, accurately, and in a manner not unpleasant for the patient. We successfully measured the pressure in 376 (94%) of 400 outpatients and failed to obtain a reading in only 24 (6%).

In 332 cases with a normal circulatory system the central venous pressure was determined by two experienced observers. In 299 (90%) of these cases the difference between the two readings was 0·5 cm. or less. In 33 (10%) the difference was greater than 0·5 cm.

The central venous pressure was determined in 352 outpatients with normal circulatory and respiratory systems and without anæmia or decreased plasma-proteins, and the results were analysed statistically. In 90% of persons in whom a normal central venous pressure is to be expected the pressure lies between +0·5 and −3·5 cm. of water in relation to a horizontal plane 5 cm. below the angle of Louis.

There was a demonstrable relationship between the central venous pressure, age, and diameter of the thorax. Since the distribution of normal results is little affected by the elimination of these relationships it is unnecessary to take them into consideration in practice.

The normal values for the central venous pressure are lower than those of the mean pressure in the right atrium, since by the modified method of Lewis the pressure is measured when the atrial pressure is at its lowest—i.e., when the end of inspiration coincides with the *x* or *y* trough of the venous pulse. If this fact is taken into consideration, there is seen to be good agreement between the normal values and the values for the mean pressure in the right atrium.

The mean pressure in the right atrium was measured simultaneously with the central venous pressure in patients with congenital heart-disease and mitral stenosis but without evidence of cardiac insufficiency. In 8 cases the difference between the two readings was 1 cm. or less; in 2 there was a difference of 1·5 cm.; and in 2 other patients a difference was found of 4 and 4·5 cm.

Factors which may influence the central venous pressure are discussed.

We are indebted to Prof. D. van Dantzig, Prof. J. Hemelrijk, and Mr. T. J. Terpstra, of the statistical department of the Mathematisch Centrum, Amsterdam, for the statistical analysis of our results, and to Dr. A. P. M. Verheugt, cardiologist of the Onze Lieve Vrouwe Gasthuis, Amsterdam, for permission to compare our method with that of cardiac catheterisation. This work was aided by a grant from the Netherlands Organisation for Pure Research.

DIAGNOSIS OF MIXED PAROTID TUMOURS

DAVID H. PATEY
M.S. Lond., F.R.C.S.
SURGEON

BERNARD H. HAND
M.B. Lond., F.R.C.S.
SENIOR SURGICAL REGISTRAR

THE MIDDLESEX HOSPITAL, LONDON

THE present is a time of change in the treatment of mixed parotid tumours. As a result of the work of Hamilton Bailey (1941, 1947, 1948) in this country and of Redon (1945, 1946), Audouin (1950), and other surgeons in France, enucleation has come under criticism as the standard surgical treatment of mixed parotid tumours, and more radical procedures, such as partial parotidectomy, superficial parotidectomy (i.e., removal of the parotid superficial to the facial nerve), and total parotidectomy, have been advocated, all with identification and preservation of the facial nerve and its branches.

Though some series of cases (Patey 1940) have been published in which the results of enucleation combined with irradiation were not too unsatisfactory, most surgeons agree that recurrence after enucleation is seen too often. Moreover, surgeons with their healthy tradition of removing tumours early and widely have always found it difficult to accept the attitude of conservatism that had grown up towards mixed parotid tumours owing to fear partly of the facial nerve and partly of infiltrative recurrences.

At present, therefore, the potentialities of the more radical operations with preservation of the facial nerve, which have been put on a sound basis technically, are being increasingly explored by surgeons all over the world. In England Kidd (1950, 1951) has published his experiences, and in France total parotidectomy seems almost to have taken the place of other operations for mixed parotid tumour. It is too early to speak of long-term results; in fact it is not yet clear whether, if enucleation is to disappear, the standard procedure to take its place should be partial parotidectomy, superficial parotidectomy, or total parotidectomy, or what are the indications for one or the other of these procedures.

DIAGNOSIS

The present paper deals not with treatment but with a prerequisite to treatment—accurate diagnosis. During the past few years we have been impressed with the inaccuracy of the clinical diagnosis of mixed parotid tumour. This is contrary to what is usually thought and taught, and, for example, candidates in final examinations are usually examined in dogmatic fashion on cases regarded as mixed parotid tumours by their examiners.

The material analysed consists of a series of consecutive cases under the care of one of us in 1940–51 which either a firm diagnosis of mixed parotid tumour was made clinically or this diagnosis was regarded as a strong possibility in the differential diagnosis. A summary of the cases with the confirmed diagnosis, where this was established, is given in the accompanying table.

CASES DIAGNOSED CLINICALLY AS MIXED PAROTID TUMOURS, 1940–51

	No. of cases	
Diagnosis not confirmed (no operation)	7	
Diagnosis confirmed:		
Primary mixed parotid tumour	18	
Recurrent mixed parotid tumour	3	
Adenolymphoma	4	
Cyst	5	
Carcinoma (including one "infiltrating mixed parotid tumour")	4	
Various:		
Chronic parotitis	1	4
Parotid lymph-gland	1	
Angio-endothelioma	1	
Neurinoma	1	
Total	45	

It will be seen that in 7 of the 45 cases the diagnosis was not established, because no operation was done. Of these 7 cases, it is probable from the subsequent course that the diagnosis was wrong in at least 2: in 1 the rapid disappearance of the lump as a result of radiotherapy led to the alteration of the clinical diagnosis to lymphosarcoma, and in the other the subsequent course suggested an uveoparotid syndrome. Of the 38 cases in which the diagnosis was established, in 18 the clinical diagnosis of primary mixed parotid tumour was confirmed, as it was also in the 3 cases of recurrent mixed tumour. But in the remaining 17 the clinical diagnosis was wrong. If we exclude the 3 recurrent cases, in which the correct diagnosis could be presumed from the previous exploration, the proportion of wrong diagnoses (17 out of 35) is approximately 50%.

That the inaccuracy of clinical diagnosis is not just a personal failing is suggested by an examination of the published reports. Thus of Kidd's 9 cases of parotidectomy with preservation of the facial nerve (he does not give his preoperative diagnosis) only 3 proved to be mixed tumours (Kidd 1950). And of Audouin's 38 total conservative parotidectomies (again the preoperative diagnoses are not given), in 12 the findings at operation excluded them from being mixed tumours (Audouin 1950). Redon, who has almost certainly had greater experience of total conservative parotidectomy than any other surgeon, tells us that in his experience the error in the clinical diagnosis of mixed parotid tumour approaches 50%.

An analysis of some of the present cases which were wrongly diagnosed clinically as mixed parotid tumour shows that the three main causes of error were cyst, adenolymphoma, and carcinoma.

Cyst clinically simulates mixed parotid tumour completely. It can be diagnosed by aspiration, but the fluid reaccumulates very quickly and, judging by our experience in the case of a patient who refused operation for eight years, nothing short of excision is curative.

Of the cysts, 2 are of special interest because after removal they were found to have tumour tissue in the wall. In one this tumour tissue was classified as an oncocytoma, and in the other as a mixed parotid tumour. In the latter case the patient, a man aged 30, subsequently migrated to Canada, and eight years later was operated on in Toronto for an infiltrating tumour with secondaries in lymphatic glands.

Adenolymphoma, again, in all our cases completely simulated clinically mixed parotid tumour, though in some cases it may simulate abscess. Contrary to what might be thought from its lymphoid structure, adenolymphoma was in our experience completely insensitive to radiotherapy.

Of the 4 cases of *carcinoma* 1 had at first all the clinical signs of a mixed parotid tumour except that it was growing rather more rapidly, and the diagnosis was only established by exploration and biopsy. In the early months of this case there was no suggestion of facial palsy. Of the other 3 cases, 1 was an extremely fibrosing carcinoma of six years' duration, and 1 an "infiltrating mixed tumour" of eight years' duration in which operation was at first refused. Both had for years no facial palsy. Neither length of history nor absence of facial palsy can be regarded, therefore, as ruling out carcinoma.

Of conditions not figuring in the present series but mimicking mixed parotid tumour tuberculosis is the most important. Redon (1946) comments specially on this fallacy. We have had 3 cases of tuberculosis of the parotid lymph-glands, not included in this series, in which a firm diagnosis of mixed parotid tumour was made clinically and the true diagnosis was not suspected until operation and biopsy. We have also had 1 case of diffuse parotid tuberculosis, but in this case the diagnosis was easily made clinically.

DISCUSSION

Possibly the clinical diagnostic error in mixed tumours of the parotid is exaggerated here by the inclusion of cases in which this diagnosis was only considered in the differential diagnosis and not firmly made. But even the latter group adds up to a considerable proportion of the cases; for example, in all the 5 cysts, all the 4 adenolymphomata, and all the 3 tuberculous lymph-glands (not included in this series) no suspicion of doubt that the condition might not be a mixed parotid tumour crossed the clinician's mind until the exploration revealed his error.

When the standard operation for mixed parotid tumour was enucleation, a false clinical diagnosis was soon rectified at operation; but, if superficial parotidectomy and total conservative parotidectomy are to be adopted as among the standard procedures for mixed parotid tumour, some preliminary diagnostic procedure seems to be indicated to avoid radical procedures for conditions in which such radicalism is not indicated. On the other hand, in carcinoma conservative operations preserving the facial nerve are not sufficiently radical; and again, if there is any doubt, the diagnostic position should be established at the beginning of the operation. The question arises of what diagnostic technique to adopt. Redon (1952) now incises as a routine all parotid tumours as a first stage of the operation and to excise a small piece for microscopy. Alternatively it may be better to do a preliminary enucleation of the tumour, where possible, with immediate microscopy. If, on the other hand, the tumour is so situated that it can be excised with a margin of normal parotid tissue round it, after identification and preservation of the branches of the facial nerve concerned, this tissue might be submitted to immediate biopsy.

We are still exploring these problems and have not yet come to any firm conclusions either on biopsy techniques or on the whole question of the position and type of radicalism indicated in mixed parotid tumours. The only point we wish to raise here is that there is a preliminary diagnostic problem.

SUMMARY

Out of 45 consecutive personal cases in which a diagnosis of mixed tumour of the parotid was made or suspected clinically, a diagnosis was established in 38.

In these 38 established cases the original diagnosis of mixed tumour was wrong in 17.

Cyst, adenolymphoma, and carcinoma were the commonest causes of error in this series. Though not represented in this series, tuberculosis of the parotid lymph-glands is also a common cause.

Adenolymphoma is not radiosensitive.

The establishment of the diagnosis should be the first step in the treatment of suspected cases of mixed tumour of the parotid if radical extirpation is contemplated.

"... a physician should marry young.... The physician who cannot study in the bosom of his family, and amidst the interruptions produced by domestic duties and professional labours, must neglect either one or the other. Early marriage, before the establishment of fixed habits of secluded study, will, in general, save a professional man from this unfortunate dilemma."—DANIEL DRAKE (1785–1852). *Practical Essays on Medical Education and the Medical Profession in the United States.* Baltimore, 1952; p. 64.

SERUM-ANTITHROMBIN LEVEL IN FIBROCYSTIC DISEASE OF THE PANCREAS

J. C. W. MACFARLANE
M.D., B.Sc. Glasg.
ASSISTANT CLINICAL PATHOLOGIST, THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON

LABORATORY confirmation of the clinical diagnosis of fibrocystic disease of the pancreas rests mainly on the estimation of the tryptic activity of the duodenal juice. Though this estimation is technically easy, and at present the final diagnostic test, it entails discomfort to the patient and demands great patience from the nurses.

Innerfield et al. (1951), describing the results of estimating the antithrombin content of the plasma in 13 cases of fibrocystic disease, concluded that this test might be "especially useful in early cases." Following their lead, I now record observations on a much larger series at The Hospital for Sick Children, Great Ormond Street.

MATERIAL

The 67 cases investigated were either those attending the hospital for routine assessment of treatment and follow-up examination or those admitted for diagnosis during the period December, 1951, to May, 1952. Their ages varied from three weeks to fourteen years (see table). In every case the clinical diagnosis had been confirmed by examination of the duodenal juice, which failed to digest gelatin at a dilution of 1 : 6 of any specimen examined.

A control group of 200 children of the same age-group was investigated at the same time. These children, suffering from no apparent lesion of the pancreas, were all attending the hospital. 14 of these had cœliac disease.

A third group, numbering 73, consisted of the remaining members of 20 families containing 22 cases of fibrocystic disease of the pancreas included in the table. It comprises 20 mothers, 19 fathers, and 34 siblings of the cases, who had all given abnormal results to the test. With this group 80 further controls were investigated.

METHODS

The method of Innerfield et al. used plasma, obtained from venous blood citrated with 3·2% sodium citrate in the proportion of 9 parts blood to 1 part citrate. This plasma was defibrinated immediately before testing.

Defibrination was obtained by adding to 1·0 ml. plasma 0·14 ml. standardised thrombin solution. To 0·9 ml. standardised thrombin was then added 0·1 ml. defibrinated plasma, and at 1, 3, 5, 10, 15, 20, and 25 minutes a sample of 0·1 ml. of the mixture was transferred to 0·2 ml. citrated normal plasma. The time taken for each sample to produce a fibrin clot in the normal plasma was noted, the entire test being carried out in the water-bath at 37°C. A normal control was run at the same time as, and five minutes after the completion of, each unknown determination. The authors recorded the result of their test plasma as "normal" when the clotting-times of the unknown and control were identical or showed minimal variation. An "elevated" titre was reported when the clotting-times of the unknown were at least twice as great as those of the control: a "low" titre was reported when the clotting-times of the unknown after five and ten minutes' incubation were less than half those of the control.

Two obvious modifications of this original method were first investigated. Firstly, plasma obtained from a finger-prick was compared with that obtained from venepuncture. 10 adults were investigated in this way, and the results showed no significant variation one from the other. When, later, cases of fibrocystic disease were similarly investigated the parallel results were again virtually identical in 5 cases. Venepuncture as a source of blood was therefore abandoned. The second modification towards a simpler technique in children was the use of serum from clotted blood in place of the "defibrinated" plasma. Parallel tests on serum and plasma obtained from the same finger-prick were performed on 28 control children and 5 cases. Once more there were no significant variations between each pair of results, and serum has been used throughout our entire investigation of cases and controls. Experience also showed that little practical value was obtained from the use of the 1-minute sample of the mixture of serum and thrombin, and that any divergence from the normal result was apparent before the 25-minute sample. Both these samples were omitted from the majority of the cases and controls examined, and they have not been recorded in the results given here.

THE RESULTS IN 67 CASES OF FIBROCYSTIC DISEASE OF THE PANCREAS

(The clotting-time of each sample is recorded as a percentage of the mean of the normals investigated the same day)

Case no.	Age (yr.)	Sample time (min.)					Case no.	Age (yr.)	Sample time (min.)

The modified technique employed has therefore been:

Standardisation of the Thrombin Solution

The method of Innerfield et al., a modification of that of Quick (1938), has been followed, using the topical thrombin of Roche.

10 ml. sterile normal saline is injected into the vial containing 1 gramme topical thrombin (5000 international units). This solution can be kept indefinitely at −20°C.

0·5 ml. of this stock solution is diluted with 16·5 ml. normal saline immediately before it is required. To 0·2 ml. normal plasma at 37°C in the water-bath is added 0·1 ml. of this diluted thrombin solution and the time taken for the formation of the fibrin clot is noted. The plasma used for this trial is obtained by venepuncture on the day of test, but stored plasma may be used for periods of up to a fortnight if kept at −60°C. The proportion of blood to 3·2% citrate is 9 : 1. The object is to produce a thrombin solution which will form a fibrin clot in the plasma in 10–15 sec., and to the original dilution of the stock thrombin solution is added saline or thrombin to achieve this end. The standardised thrombin should be made fresh on each day of test, and when not in use should be kept chilled.

Collection of Serum

Blood collected from a finger-prick is allowed to clot at room-temperature and the serum separated by centrifugation. Enough serum for a test can be obtained from 0·5 ml. blood.

Performance of the Test

The entire test is carried out at 37°C in the water-bath. With practice it is easily possible to perform four simultaneous estimations. Each test requires a rack of seven tubes. Into tubes 2, 3, 4, 5, and 6 is pipetted 0·2 ml. normal plasma. Tube 7 contains the serum to be tested. Into tube 1 is pipetted 0·9 ml. standardised thrombin solution, and as soon as possible 0·1 ml. of the test serum is added to it. A stop-watch is started at this addition. After incubation of this serum-thrombin mixture for 3, 5, 10, 15, and 20 minutes, 0·1 ml. samples of it are transferred to the plasma in tubes 2, 3, 4, 5, and 6 respectively, and the times taken for the fibrin clot to form in each is noted.

Recording of Results

For technical reasons there is a slight variation in the results obtained in normal controls examined on any one day and even contained in the same rack. The plasma used, the concentration of the standardised thrombin solution, and the fluctuations in the temperature of the water-bath all produce even wider day-to-day variations. Hence no absolute comparison between the results obtained in one case and those obtained in another is possible, and it has been found that the results are best expressed as the percentage of the mean of the normals tested on the same day, each sample being thus compared. Comparison of cases is then possible.

RESULTS

The table shows the results obtained in the 67 cases investigated, the clotting-times of each sample being expressed as percentages of the mean of the normals examined on the same day. It will be seen that 60 cases showed a definite decrease in the antithrombin content of their serum compared with the normal controls. Fig. 1 shows the scatter of these results, and compares it to the scatter of 200 normal controls. In the latter the variation shown is within experimental error. In the figure the upper and lower limits found at each sample time are shown, while the shaded area in each group shows the variations between which 75% of the sera investigated fell. The lines within each shaded area mark the boundaries of 50% of the sera studied. It will be seen that there is a considerable difference between the results obtained in 75% of the cases and those obtained in the 200 controls, while even the highest reading obtained at the 15-minute and 20-minute samples of the 60 cases is appreciably less than the lowest reading at the same sample time obtained in the

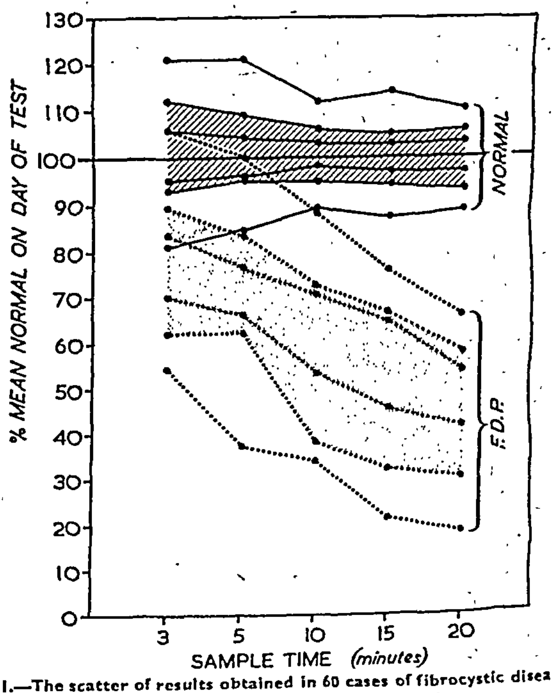

Fig. 1.—The scatter of results obtained in 60 cases of fibrocystic disease of the pancreas and in 200 normal controls.

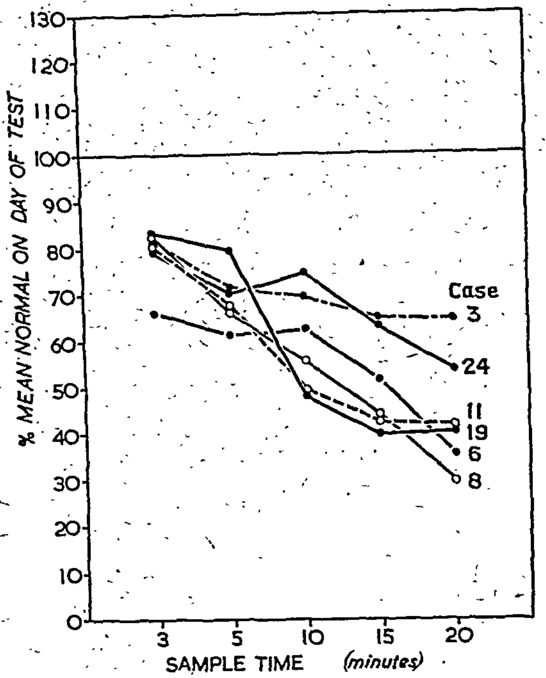

Fig. 2.—The typical results obtained in 6 cases of fibrocystic disease of the pancreas of different ages.

control group. The remaining 7 cases (cases 20, 45, 46, 52, 54, 66, and 67) listed in the table gave results which fell within the limits of those obtained in the control group, as shown in fig. 1. From both the table and fig. 1 it is obvious that the most valuable information can be gained from the 15-minute and 20-minute samples, and for practical purposes it would appear that these samples alone need be studied.

Fig. 2 shows the curves obtained in 6 cases, expressing the sample times as percentages of the mean normal (100%). These curves are typical of the entire series tested, except the 7 cases which gave normal results, and are selected only in that they are the results obtained in 6 children of varying ages.

Investigation of the 20 families containing cases of fibrocystic disease showed no deviation from normal in any of the 73 sera tested, while of a further series of 80 normal controls examined only 1 has given results which are indistinguishable from those found in 90% of the cases.

Experiments have been made into the possibility of storing sera for this test. Sera from 3 cases and from 3 controls were stored for up to a fortnight at room-temperature, in the refrigerator, at —20°C, and at —60°C. The antithrombin content of these sera was estimated frequently during this period and no variation in the results was found at any time, one from the other or in comparison with fresh sera from cases or controls. The findings in children who had been treated with pancreatin and oral antibiotics for a considerable period were similar to those in children admitted for diagnosis whose sera were examined before therapy began. The examination of the serum from one case from week to week has shown very little variation, well within that seen when two cases are compared. This applies equally to the results obtained in another case which has given normal figures over a considerable period.

DISCUSSION

The uniformity of these results is at variance with the findings of Innerfield and his colleagues. These authors reported a decrease in the antithrombin content of the plasma in only 1 of their 13 cases, an infant of three weeks whose diagnosis was confirmed at necropsy shortly afterwards. Raised titres were found in 3 children aged five, seven, and nine months, while the remaining 9 cases, all over three years of age, gave normal results. They postulated that the differences in antithrombin titres coincided with the different stages of the disorder of the pancreas. Stage I, in which the antithrombin content was reduced, was that of pancreatic duct atresia, the histological picture being one of acinar atrophy and fibrosis with hyperplasia of the epithelium of the pancreatic ducts. Stage II represented the transition period of interstitial pancreatitis, and at this stage the antithrombin content of the plasma was elevated, as the same authors had found it to be in acute pancreatitis. Stage III was that of the classical picture of nutritional and respiratory components, the histological picture being one of homogeneous contracted fibrous tissue almost devoid of functioning acini. In this stage the antithrombin content of the plasma was normal. Though their 9 cases over the age of three had all given normal titres, they added the rider that the titre might be influenced by the action of the few isolated acini as yet unaffected by fibrosis and that "it is possible that in total pancreatic fibrosis there would be a concomitant depression in antithrombin titer."

The importance of this rider is obvious from the results of the present series, where 60 of 67 cases showed lowered serum antithrombin titres and only 7 cases gave normal titres. Clinically all the patients showed classical features of nutritional and/or respiratory symptoms. Though 13 of them were under one year of age and a further 15 were less than three years old, none showed the elevation of antithrombin titre suggested by Innerfield et al. as corresponding to stage II of the disease. No confirmation that the antithrombin content reflects the pathology of the pancreas is present in this series.

What is apparent, however, is the great potential value of the test as a confirmation of the clinical diagnosis. In 90% of the cases tested the results have been positive, while in a total of 353 controls there has only been 1 "false" positive. In this case, a girl of eight years, suffering from chronic eczema, has given consistently low antithrombin levels in her serum over a period of three months. She presents no symptoms of fibrocystic disease of the pancreas, and the proteolytic activity of her stool is within normal limits while the tryptic activity of her duodenal juice is at the lower limit of normality (gelatin digested completely at a dilution of 1 : 25). The link between her serum abnormality and that present in cases of fibrocystic disease requires investigation beyond the scope of this paper. Though a series of investigations into the possible rôles of blood trypsin and heparin content are being undertaken, at the moment there is insufficient evidence to implicate either of these factors in the ætiology of abnormal antithrombin contents.

The test appears to offer a very practical, if empirical, method of confirming the clinical diagnosis. It is simple technically, the results are repeatable, and it can be performed on as little as 0·5 ml. blood obtained from a finger-prick. It appears, in our experience, to have a reliability comparable to that of duodenal intubation, and from the viewpoints of the patient and of the nurses much would be gained if it were generally employed to confirm the diagnosis in suspected cases, and if duodenal intubation were resorted to only where the antithrombin content falls within normal limits.

SUMMARY

The serum-antithrombin level was estimated in 67 confirmed cases of fibrocystic disease of the pancreas and in 353 normal controls, 73 of whom were from 20 affected families. Of the 67 cases, 60 (90%) showed a lowered antithrombin level and 7 gave normal results: of the controls only 1 showed an abnormal (depressed) level.

These results are contrasted with those of Innerfield et al. who published the original method.

It is suggested that the test is sufficiently reliable to be used for confirmation of the clinical diagnosis, and that duodenal intubation should be reserved for suspected cases in which the antithrombin content of the serum lies within normal limits.

I am indebted to Dr. I. A. B. Cathie, in whose laboratory this work was performed, for criticism and advice, and to the physicians for access to their cases. I am especially indebted to Dr. A. P. Norman for access to the cases attending the Fibrocystic Clinic, and to Mr. G. W. Cecil for much technical assistance.

LOCAL USE OF ANTIBIOTICS IN CHRONIC SUPPURATION OF THE MIDDLE EAR AND MASTOID

WITH PARTICULAR REFERENCE TO TERRAMYCIN

THE purpose of the investigations reported here was to determine the relation between (1) the organisms occurring in chronic suppuration of the middle ear and mastoid and (2) the sensitivity and clinical response of these infections to the various antibiotics. Could one determine the ideal drug in a given case by a knowledge of the sensitivity of the organisms to the antibiotics? And how could one determine the drug of choice when the organisms were sensitive in vitro to more than one?

We treated fifty-four cases of chronic suppuration with four antibiotic powders, each in a sterile lactose base: penicillin, streptomycin, chloramphenicol, and terramycin, limited quantities of the last-named having been made available to us for the investigation.

METHOD

At the initial visit the affected ear was cleaned by dry-mopping with cotton-wool on a Jobson-Horne probe, and a swab was taken for bacteriological examination. The bacteriologist determined in every case the organisms grown on culture and the sensitivity of each organism to the four antibiotics mentioned above. The ear was treated by simple dry-mopping until the report was available and the appropriate drug determined. In most cases, this drug was then applied locally by insufflation in powder form by the method of "frosting" and as often as the patient could attend; in some cases, however, we used a drug to which the organisms were insensitive in vitro. If there was no response to treatment after a reasonable period, a fresh swab was taken and another antibiotic used when the sensitivity was known.

The bacteriological studies were made by Dr. C. W. Morley and Dr. J. R. May, using the method they have already described (May and Morley 1952).

The antibiotics were all prepared in a sterile lactose base in the following concentrations: penicillin 2000 units per g., streptomycin 1%, chloramphenicol 25%, and terramycin 2%.

RESULTS

The follow-up period has varied, but we have not considered any patient to have improved unless a continuously discharging ear had remained dry for at least a month. Many cases were followed up for 2, 3, or 4 months.

Four main groups are distinguished:

Uncomplicated chronic suppurative otitis media.
Chronic suppurative otitis media complicated by granulations.
Discharge following the radical mastoid operation and its modifications.
Discharging fenestration cavities.

For purposes of comparison the results are further divided into three subgroups:

(*a*) Cases treated with terramycin only.
(*b*) Cases treated with penicillin, streptomycin, and chloramphenicol, but not with terramycin.
(*c*) Cases treated with terramycin and other antibiotics.

Uncomplicated Chronic Suppurative Otitis Media

Eighteen cases were treated.

(*a*) Seven of these were treated with terramycin only. Six became dry, after an average of 3·5 insufflations, and have remained dry for 2–3 months. These included one case in which *Proteus vulgaris* sensitive in vitro only to chloramphenicol was grown on culture. The one remaining case was still discharging when last seen, but the patient did not attend for further treatment or follow-up.

(*b*) Five cases were treated with penicillin or chloramphenicol. All of them have remained dry for at least 2 months. In one of them *Bact. coli* sensitive to streptomycin, chloramphenicol, and terramycin but not to penicillin responded rapidly to insufflation of penicillin powder. One case with mixed organisms responded to dry-mopping alone.

(*c*) Six cases were treated with terramycin and other antibiotics. Five of them became dry rapidly with terramycin, after an average of 3·4 insufflations, when treatment with other antibiotic powders over periods ranging from 3 days to 7 weeks had failed, and these have all remained dry for 1–3 months. The one remaining ear became dry with 2 insufflations of chloramphenicol powder after terramycin had failed.

Chronic Suppurative Otitis Media Complicated by Granulations

Seven cases were treated. In each case the granulations were cauterised with fused silver nitrate on a probe before the powder was insufflated.

(*a*) Four cases were treated with terramycin only. All were dry when last seen, although in only one of them was one of the organisms reported as sensitive to terramycin in vitro.

(*b*) Two cases were treated with chloramphenicol. Both have been dry for at least 2 months, and both were sensitive to the drug in vitro.

(*c*) One case was treated with terramycin and chloramphenicol. It responded to 1 insufflation of chloramphenicol, after terramycin insufflated 4 times on alternate days had failed.

Discharging Radical Mastoid Cavities

Seventeen cases were treated.

(*a*) Two cases were treated with terramycin only. Both responded to treatment with terramycin, although in each case organisms insensitive to it in vitro were grown on culture. One has remained dry for 3 months; the other recurred after 1 month but responded to 2 further insufflations of terramycin on alternate days and has remained dry for a further month.

(*b*) Five cases were treated with chloramphenicol. Four of them became dry, after an average of 6·25 insufflations, and have remained dry for 2–3 months. The patient who was not dry when last seen did not return for treatment after 3 attendances. This infection was due to a mixed growth of *Pseudomonas pyocyanea* sensitive only to terramycin and *Pr. vulgaris* insensitive to all the antibiotics.

(*c*) Ten cases were treated with terramycin and other antibiotics. Of this number seven became dry for at least 2 months. Six of them cleared, with an average of 3·4 insufflations of terramycin, after chloramphenicol had failed over periods of 3–16 days. One case responded to chloramphenicol after treatment with terramycin had failed.

Discharging Fenestration Cavities

Twelve cases were treated.

(*a*) Four were treated with terramycin only. All of them became dry after treatment with terramycin, but one recurred. This has received further treatment with terramycin and was dry again after 2 insufflations.

(*b*) One case was treated with streptomycin and chloramphenicol, finally responding to chloramphenicol after earlier failure with this drug and subsequently with streptomycin. The ear has remained dry for 4 months.

(*c*) Seven cases were treated with terramycin and other antibiotics. They all became dry, with an average of 2·7 insufflations of terramycin, after they had failed to respond to treatment with other antibiotics for periods of 3–37 days. Chloramphenicol had been used unsuccessfully in all of them before terramycin was used. In three of the cases, all due to *Ps. pyocyanea*, the organisms were sensitive to terramycin only.

Summary

Fifty-four patients with discharging ears were treated by the local insufflation of four antibiotic powders —penicillin, streptomycin, chloramphenicol, and terramycin. Eighteen were uncomplicated cases of chronic suppurative otitis media, seven were cases of chronic suppurative otitis media complicated by the presence of granulations, seventeen were discharging radical mastoid cavities, and twelve were discharging fenestration cavities.

Three cases have been dry for 4 months, sixteen for 3 months, and twenty-three for 2 months. Complete failure occurred in only two cases, both of which were discharging radical mastoid cavities. One of them had a stenosed external auditory meatus, and the other has not attended for follow-up, but never became dry while he was under observation, and had an infection with *Pr. vulgaris* which was resistant to all the antibiotics used.

BACTERIOLOGY

The incidence of the organisms grown on culture was :

Staphylococcus aureus	19 cases
Pr. vulgaris	16 ,,
Ps. pyocyanea	14 ,,
Bact. coli	9 ,,
Hæmolytic streptococci	3 ,,
Pneumococci	1 ,,

Of the sixteen cases in which *Pr. vulgaris* was grown on culture, three were insensitive to penicillin, streptomycin, chloramphenicol, and terramycin.

Of the fourteen cases in which *Ps. pyocyanea* was grown on culture, thirteen were sensitive to terramycin only.

SUMMARY AND CONCLUSIONS

Fifty-four discharging ears were treated by local insufflation of antibiotic powders. These were cases of chronic suppurative otitis media and discharging radical mastoid and fenestration cavities.

The bacteriology of these infections was studied, and the sensitivity of the organisms to penicillin, streptomycin, chloramphenicol, and terramycin was determined.

There was no constant relation between the sensitivity of the organisms and the clinical response to the drug of bacteriological choice, for in fourteen cases the drug of choice failed to bring about any improvement, and in no fewer than ten cases terramycin was used successfully in treating infections which were insensitive to it in vitro.

This inconsistency may have been due in some cases to changing flora. For example, in one case *Staph. aureus* and *Bact. coli* both sensitive to chloramphenicol in vitro were grown on culture. Application of this drug 7 times, at weekly intervals, did not cure the discharge but after 7 weeks terramycin was applied (after taking a swab) and the ear became dry and has remained dry for 3 months. This final swab, taken before applying the new antibiotic, grew *Ps. pyocyanea* sensitive only to terramycin in vitro.

Further, there was an incompatibility between the concentration of the drugs applied locally in this series and their concentration in the test-plates, for the latter were specifically prepared to approximate to the concentrations revealed in the blood when they were administered systemically. Hence it is possible that some of the organisms reported as insensitive to the antibiotics in the concentrations used in the plates might have been sensitive in vitro to the much higher concentrations that were used locally in our cases.

However, these arguments leave unexplained many of the cases in which there was no apparent relation between the sensitivity of the organisms and their response to the drugs applied.

It therefore seems that one is justified in treating all such cases in the first instance with the particular antibiotic which is found by experience to yield the best results.

Terramycin has undoubtedly given the most satisfactory results in this series ; for, whereas 47% of the twenty-eight cases treated with chloramphenicol became dry, 83% of the forty-one cases treated with terramycin became dry. Further, in a selected group of fourteen cases in which the organisms were sensitive to both chloramphenicol and terramycin, twelve cases responded to terramycin after chloramphenicol had failed, whereas only two cases responded to chloramphenicol after terramycin had failed. Of the twenty-four cases in which terramycin *and* other antibiotics were used eighteen responded to terramycin after other antibiotics had failed.

Definite conclusions are not warranted with so small a series as the present one, and with so short a follow-up period ; but terramycin has given results so much superior to those obtained by any of the other antibiotics that we feel that it is worthy of further extensive trial now that it is becoming more generally available.

This investigation was undertaken at the suggestion of our chief, Mr. J. F. Simpson, to whom we are greatly indebted for his encouragement and advice ; we are grateful also to him and to Mr. I. G. Robin for referring their cases to us. Dr. C. W. Morley and Dr. J. R. May, of the Wright-Fleming Institute of Microbiology, have kindly made all the bacteriological examinations reported here, and to them we extend our sincere thanks.

"The non-material or internal conditions [of a dwelling] are more difficult to describe and to remedy. By far the most urgent is the relief of overcrowding and the early achievement of the ideal of *one family, one dwelling*. The second condition, which follows hard on the heels of the first, is the intelligent distribution of family life to make the best use of the house as a whole and to give each member a personal 'holding,' however small, within the house. The third condition is the promotion of the family spirit, a sense of independence within each household. . . . In a well-knit family there are interesting jobs for everyone to do ; each member feels that he has a personal stake in the house, and a part to play in making it a home. In present conditions we need to pay more attention to the inward grace of family life."—Prof. J. M. MACKINTOSH, F.R.C.P., *Housing and Family Life*, London, 1952.

THE SITE OF ACTION OF THE TOXIN IN LOCAL TETANUS

IN a series of papers which have received widespread attention Abel et al. (1935a, b, and c, 1938) have explicitly expressed their view that in local tetanus the toxin acts peripherally at the myoneural junction. This conception of the pathogenesis of tetanus is directly at variance with that proposed by Meyer and Ransom (1903) and widely accepted by other workers. The main thesis of Abel and his Baltimore colleagues is based on their opposition to the earlier belief that in local tetanus the toxin passes centripetally from the focus of infection or depot of injection to the central nervous system by way of regional motor nerve-trunks. Abel reviewed the evidence for this latter view, and after considering seriatim the possible participation in such a process of the various components of nerves—axones, intraneural tissue spaces, and neural lymphatics—concluded that none of these structures could be accepted for such a rôle. Since the issues raised in this problem are wider than the mere mechanism of the intoxication in this disease—for they also concern the possible central transference of other noxious agents by the same route—the pathogenesis of local tetanus has deservedly been the subject of many experimental investigations. The present paper forms one of a series designed to throw further light on these questions; it is specifically directed to clarifying the site of action of tetanus toxin.

The spastic contraction of the affected muscles in the early stages of local tetanus is associated with a pronounced exaggeration of their activity as recorded electromyographically. If the spasticity is only three or four days old, both the contraction and the electrical activity cease promptly on the induction of general anæsthesia. Alone this observation affords no means for discriminating between the two hypotheses of central or peripheral intoxication, for the action of the narcotic might be located either in the central nervous system or at the myoneural junction. But if an experimental procedure is used which, without causing any impediment to the passage of nervous impulses, prevents the access to the affected limb of a generally circulating narcotic, the course of the electromyographic tracing immediately after the administration of an anæsthetic would indicate whether the spasticity depended on a disturbance of a central or a peripheral mechanism. For if the intoxication is peripheral, as Abel and his colleagues believed, the exclusion of the myoneural junctions in the spastic muscles from the action of the narcotic would permit the typical electromyographic activity of the tetanus to continue unabated; whereas, if the toxin acted centrally in the spinal cord, both the contraction and the electrical activity of the spastic muscle should cease for the duration of the anæsthesia. Such a temporary isolation of a limb from the effects of a narcotic injected into the general circulation through a marginal ear vein can readily be effected by the obliteration of its main arteries by the inflation of a sphygmomanometer cuff placed at a site well proximal to the affected muscles whose electrical activities are to be recorded. The brief period of vascular occlusion needed in such experiments has no detrimental effect on the function of the regional nerves; hence, while the limb muscles are shut off from the main circulation, and consequently protected from the action of any drug that may then be introduced into it, they remain in fully functional nervous connection with the spinal cord.

In anticipation of the findings described below it may be stated here that the protection of the myoneural junctions in the affected limb from the circulating anæsthetic does not prevent the termination of both the muscular spasms and the electrical activity. The inference to be drawn from this finding is that in local tetanus the toxin must have a central seat of action, as Meyer and Ransom believed, and not an exclusively peripheral one, as Abel and his associates thought. An important corollary to this finding is that the toxin must have spread to the central nervous system from its depot in the muscles; and, since its hæmic transport can be precluded by the injection of an immunological excess of antitoxin into the blood-stream, this spread can only have taken place by way of the regional motor nerve-trunks. The present experiments thus give support to the belief that tetanus toxin, and possibly other agents too, can pass centrally to the spinal cord by this route.

MATERIALS AND METHODS

Animals.—Adult albino rabbits weighing 2–3 kg. and of either sex were used.

Toxin.—The preparation was the same as that described previously by Wright et al. (1950). A standard dose of 0·1 mg. in 0·2 ml. of 0·9% sodium chloride was injected into the centre of the fleshy belly of the left gastrocnemius muscle with a 1 ml. tuberculin syringe and a no. 20 needle. This sublethal dose gave a local tetanus which appeared in 48–72 hours and showed little or no extension of the intoxication to the opposite side.

Electrodes.—The recording electrodes were small pure silver spheres, 1·5 mm. in diameter, formed by fusing short lengths of wire. These were soldered to fine enamelled copper wires, which were then inserted into thin 'Polythene' tubing, 1·0 mm. in external diameter, so that only the silver spheres were exposed. Two such electrodes were used for each gastrocnemius muscle; one was placed over the centre of the lateral head, and the second 2 cm. lower on the body of the muscle. The electrodes were placed under the skin by first passing a large-bore needle subcutaneously from a site of insertion near the ankle to a point of emergence slightly above the position selected for the electrode head. The insulated electrode lead was passed backwards through the needle, which was then withdrawn to leave the silver head approximately in position between the skin and the epimysium. Its final location was next correctly adjusted, and its head fixed in place with a skin stitch. The leg, together with the emerging polythene-covered leads, was wrapped with gauze bandage made adherent with "plastic skin." An earth lead was formed by an electrode lightly clipped to an area of shaved skin on the back.

Amplifier and recording apparatus.—The pairs of electrodes were connected to a two-channel condenser-coupled amplifier with balanced input stages. Both channels were connected to a Cossor 1049 double-beam oscillograph. A second similar double-beam tube in parallel with the oscillograph was used

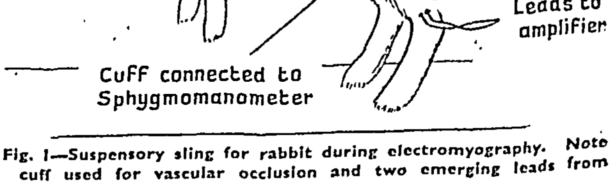

Fig. 1—Suspensory sling for rabbit during electromyography. Note cuff used for vascular occlusion and two emerging leads from recording electrodes.

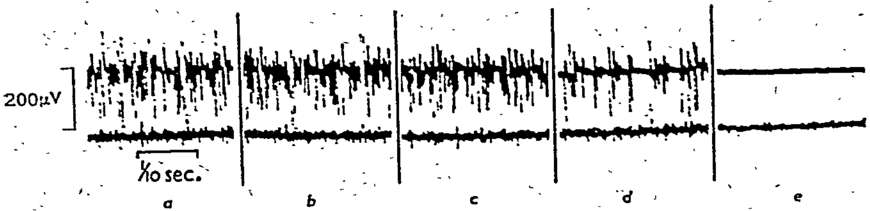

Fig. 2—Electromyographs from tetanus (upper trace) and normal (lower trace) gastrocnemii, showing effect of anæsthesia in terminating action potentials: *a*, at 5 sec. before nembutal injection; *b*, immediately after injection; *c*, *d*, and *e*, at 5, 10, and 15 sec. afterwards respectively. Nembutal injection took about 8 sec.

for photographic recording on a continuous-film camera. The gain of both amplifiers was adjusted to 1·5-cm. per 100 µV screen deflection. A further small oscilloscope tube enabled time and other signals to be photographed simultaneously.

Anæsthesia.—A dose of 'veterinary Nembutal' 25 mg. per kg. of body-weight consistently abolished the electrical activity of both normal and tetanus muscles, and was used in all the experiments. For the insertion of the electrodes this anæsthetic was fortified with open ether.

Suspensory sling for animals.—For electromyography the rabbits were supported in a horizontal position in a sling made of a fold of strong calico with four holes for their legs (fig. 1); the sling was arranged so that the claws of the hind legs just touched the table. The rabbits soon became accustomed to this posture, in which they appeared to be comfortable. In normal rabbits thus slung, action potentials from the gastrocnemius muscles soon ceased.

Vascular occlusion.—To effect the temporary interruption of the circulation through the hind limb a small sphygmomanometer cuff (10 × 5 cm.) was placed round the rabbit's thigh and inflated to a pressure of 200 mm. Hg. The duration of such an occlusion never exceeded two minutes. The efficacy of this procedure in preventing the access of blood to the limb was tested by injecting 30 µC of I^{131} into an ear vein and recording the gamma radiation from the foot during the period of occlusion and shortly after the release of pressure in the cuff. In five successive rabbits the counts obtained during occlusion were never more than 2% of those obtained after free circulation had been restored.

RESULTS

Effect of Anæsthesia on Local Tetanus with Unobstructed Limb Circulation

During the first few days of local tetanus electromyographic records from affected muscles show several distinctive features. A significant sign of impending intoxication is exaggeration and prolongation of the electromyographic activity after such external stimuli as touching or noise. Though the reaction in normal muscles soon subsides after the termination of stimulation, the activity in the affected muscles persists with slow decrement over several seconds. As the limb gradually becomes spastic, electromyographic responses become more and more easily evoked, until eventually they become continuous and apparently spontaneous. It is significant that in this phase of local tetanus, which Ranson (1928) named the "hypertonic stage," both spasticity, which by then has become severe, and action potentials can be promptly terminated by general anæsthesia. The rapid loss of electromyographic activity that follows the intravenous injection of nembutal is shown in fig. 2. Within 10 seconds of the start of the injection the frequency of the action potentials in the affected gastrocnemius has diminished, and by 20 seconds all signs both of spasticity and of electrical activity have ceased. As the rabbit recovers from a moderate dose of the anæsthetic, the exaggerated signs of both mechanical and electrical muscular activity return and, by the end of 2 hours, reach their pre-anæsthesia levels.

Effect of Anæsthesia on Local Tetanus after Occlusion of Limb Circulation

The application, by means of an inflated cuff, of an external pressure of 200 mm. Hg to the hind limb has no detrimental effect on the conduction of impulses down the motor nerve-trunks. Fig. 3 shows an electromyographic record taken from a gastrocnemius muscle in local tetanus immediately before, and at four successive intervals of 15 seconds after, the inflation of a cuff placed proximally on the thigh. The absence of any change in the frequency of the action potentials from the muscle shows that, for a period of a minute at least, this procedure is without significant effect on the local spasticity. Such a finding might be anticipated from the observation of Causey and Palmer (1949) that the application for 20 minutes or more of such pressures directly to the motor nerve to the gastrocnemius muscle in rabbits seldom affects its power of conducting impulses.

When nembutal is injected intravenously into a rabbit with local tetanus, the circulation of whose affected limb has been occluded a few seconds beforehand, the action potentials decrease in frequency and finally cease in the same way as had been seen formerly in similar rabbits whose circulation was unobstructed. The electromyographic records of three rabbits submitted in immediate succession to vascular occlusion and intravenous nembutal anæsthesia are shown in fig. 4. From them it can be seen that the termination of the exaggerated electrical activity of muscles in local tetanus occurs quite independently of whether or not the anæsthetic agent has access to their myoneural junctions.

As the electrical complexes diminish in frequency during the induction of anæsthesia, their individual characteristics usually become discernible. It can be seen from fig. 5 that each diphasic action potential has the character of a single motor-unit response with an amplitude of about 300 µV and occupies some 6 or 7 millisecs. These figures are comparable with those found by Weddell et al. (1944) for single motor-units in man. Our records give no indication that in local tetanus there is any after-discharge at the myoneural junction of the kind described by Harvey (1939) as following a single electrical stimulus to the cut motor nerve, and regarded by him as demonstrating a peripheral action of the toxin. The present findings, however, are in conformity in this respect with those of Göpfert and Schaefer (1940), Acheson et al. (1942), and Perdrup (1946), all of whom after a careful electromyographic study of local tetanus were unable to confirm Harvey's observation and regarded his "after-discharge" as an artefact.

DISCUSSION

The termination of the spasticity and the action potentials of affected muscles in local tetanus by an intravenously injected anæsthetic whose entry into the limb is prevented by arterial occlusion shows that the source

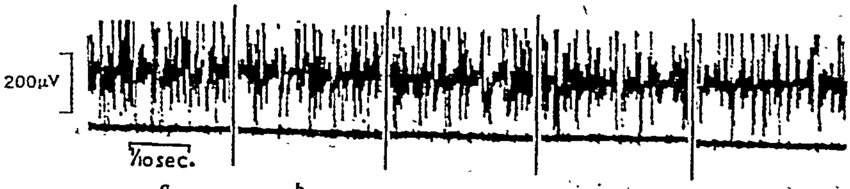

Fig. 3—Electromyographs from tetanus (upper trace) and normal (lower trace) gastrocnemii, showing that inflation of pressure cuff on thigh has no effect on muscle action potentials: *a*, immediately before inflation; *b*, *c*, *d*, and *e*, at 15, 30, 45, and 60 sec. afterwards respectively.

This suppressive action has been found to take place even if the circulating anæsthetic is prevented from reaching the affected muscles by the inflation of a pressure cuff on the thigh.

From this latter observation it is inferred that the source of the exaggerated mechanical and electrical activity in such muscles lies within the central nervous system and not peripherally at the myoneural junctions.

We wish to thank Mr. A. Nightingale, of the physics department, Guy's Hospital Medical School, for his help in designing the recording apparatus.

POLYARTERITIS NODOSA AFTER THIOURACIL

P. G. DALGLEISH

M.D. Lond., M.R.C.P.

TUTOR IN MEDICINE, UNIVERSITY OF BRISTOL

SHORTLY after the introduction of thiourea derivatives in the treatment of thyrotoxicosis it became clear that these drugs often produced toxic effects. Fowler (1946), in a review of 1573 patients treated with thiouracil, found such complications in 13·7%, of which the most serious was agranulocytosis, which was responsible for all the 7 deaths. He found no instance of polyarteritis nodosa, and so far there have been few other reports of this complication.

CASE-RECORD

A housewife, aged 44, developed symptoms of thyrotoxicosis in September, 1950. She was given iodine for seven months, at the end of which time she was worse. She was then given thiouracil 100 mg. three times a day and began to improve. In May, 1951, she was referred to the outpatient department with obvious signs of thyrotoxicosis. She was flushed and perspiring and had slight tremor of the hands. There was a little proptosis of the eyes with some lid lag. Her pulse-rate was 120 and blood-pressure 160/85 mm. Hg. Her thyroid gland was uniformly enlarged and vascular. She was advised to continue taking thiouracil.

Early in August,* 1951, on return from holiday, a rash appeared on her legs. Her doctor thought this was severe sunburn and that she also had some phlebitis in the legs, for there was œdema of the feet and ankles. She had some fever, but no other abnormal signs were noted. Thiouracil was discontinued. The patient went to bed and received local treatment, and after ten days, feeling better, she got up and began to take thiouracil again.

About a fortnight later, on Sept. 3, she complained of weakness, malaise, and pain in the legs. She had pyrexia and was put back to bed. Thiouracil was again discontinued. The next day she had cramping pains and pins-and-needles in her calves. Dark-red patches appeared on the dorsum of the feet. On this day her feet became weak, and during the next few days the weakness gradually spread up the legs, being worse on the right. At the same time she lost the use of her hands, and the right arm became weak. She vomited several times during this period. Pyrexia (99°–103°F) continued. Because of this she was given 'Sulphatriad,' about 20 g. in the next five days without any improvement in her condition. Nine days after the onset of the episode she was admitted to hospital.

On admission she was very ill. Her temperature was 101°F, pulse-rate 120, and respirations 35 per minute. Her blood-pressure was 100/60 mm. Hg, but otherwise the cardiovascular system was normal. Her respiratory system and abdomen showed no abnormality. She was confused, and it was difficult to hold her attention, which made subjective testing difficult. There was flaccid paralysis of the arms and legs, with loss of tendon-reflexes. All forms of sensation were lost on the arms distal to the middle of the upper arm and on the legs from the mid-thigh downwards. Sensation appeared to be normal on the trunk. The respiratory movements were fairly good. The cranial nerves were normal, but the right optic fundus showed fullness of the veins and blurring of the disc margin. Over the dorsum of each foot were some dark-purple indurated areas.

Investigations.—The urine contained a little protein and some pus cells but no red cells, casts, or organisms, and no porphyrin derivatives. A white-cell count showed 39,000 per c.mm. (polymorphs 95%). Lumbar puncture produced clear cerebrospinal fluid under a pressure of 180 mm. and containing 135 white cells per c.mm. (polymorphs 68%, lymphocytes 30%), protein 30 mg. per 100 ml., and a normal amount of glucose. Culture of the fluid was sterile, the Wassermann reaction was negative, and the colloidal-gold curve was normal.

Progress.—Next day she was worse and had difficulty in breathing. She was put in a Drinker respirator, where she remained for four days until her death. During this time her condition steadily deteriorated and she became more confused and finally unconscious. Her fever and tachycardia gradually settled, but signs of bronchopneumonia appeared, though penicillin was given to try to prevent chest infection. Another lumbar puncture, the day before death, showed a further increase in the number of white cells and a slight increase in the protein.

Necropsy thirty-eight hours after death showed extensive bronchopneumonia. Macroscopic changes were seen in several organs. There were two patches of discoloration close to the anterior descending branch of the left coronary artery. The kidneys were enlarged and congested, and there was hæmorrhage into their pelves; yellow patches resembling pyelonephritis were seen on the cut surface. No obvious changes were seen in the brain, spinal cord, or posterior-root ganglia. Both sciatic nerves, 15 cm. below the sciatic notch, were swollen, hyperæmic, and hæmorrhagic, and this change extended down the popliteal branches.

Histologically sections of numerous parts of the brain, spinal cord, and posterior-root ganglia showed acute arteritis throughout the small vessels, with necrosis of the wall and abundant fibrin exudate surrounded by polymorphs. No other lesion was observed in the central nervous system. The sciatic and popliteal nerves showed the same lesions to a much greater extent, there being profuse hæmorrhages with gross œdema and widespread arteritis of all the vessels. The two discoloured patches on the anterior descending left coronary artery were similar foci of arteritis. Here again it was the small arteries that were involved, but the main anterior descending branch showed slight inflammation in one place. The lesions in the kidneys were not due to infection but to an acute polyarteritis causing patches of infarction. The chief impact was on the afferent arterioles and the smaller branches of the interlobular arteries, but to a lesser extent similar changes were present in the arcuate arteries. In none of the organs was there any sign of healing of the arteritic lesions. Histological examination of the thyroid showed that there was a uniform hyperplasia of the acini, which were dilated and contained poorly staining colloid; in addition there was a very intense arteritis of all the small arteries. These findings thus established the diagnosis of acute polyarteritis nodosa which appeared to be of brief duration.

DISCUSSION

The first case of this type of complication of thiouracil therapy was recorded by Gibson and Quinlan (1945), who described the case of a woman of 46, treated for thyrotoxicosis with thiourea for thirty-five days, who then developed fever and conjunctivitis followed by a peripheral neuritis. She died in two weeks, and at necropsy evidence of polyarteritis was found. This patient had also been given Lugol's iodine for fourteen days before the onset of symptoms. In view of the report by Rich (1945) of polyarteritis in a woman with thyrotoxicosis treated with iodine, the possibility of iodine as an ætiological factor should perhaps be considered. Barnum et al. (1951) reported on a woman who undoubtedly developed polyarteritis three weeks after restarting treatment for thyrotoxicosis with thiouracil and iodine. Several months before this she had had both these drugs for nine weeks. When the antithyroid therapy was stopped, her polyarteritis gradually settled. McCormick (1950), however, had a case in which the patient died from widespread polyarteritis nodosa which developed six days after the inadvertent restarting of propyl thiouracil for a third course of treatment. She had been shown to be sensitive to the drug some months before, when a test dose was given. This test was made with only 50 mg. and was done because she had shown untoward symptoms on beginning a second course of the drug. Neither this patient nor that of Barnum et al. had any unusual symptoms during the first course of treatment. On the other hand, Foss (1950), reported generalised aches, pains in the legs, swelling of the ankles, and pyrexia in a thyrotoxic woman treated with 2-mercapto-imidazole for forty-seven days uninterruptedly. These symptoms disappeared when the drug was stopped, and twenty-six days later, there being no abnormal signs, the treatment was restarted. Sixteen days later the patient developed pyrexia, polyneuritis, and evidence of renal involvement. Polyarteritis was diagnosed, but never proved histologically, because she recovered and a biopsy specimen was negative. Two days before her illness began she had been switched from 2-mercapto-imidazole to methyl thiouracil because of shortage of the former drug.

In the present case there is strong circumstantial evidence that thiouracil was responsible for the development of the polyarteritis. The patient had been taking the drug for about four and a half months when she developed an unusual rash and swelling of the legs and became febrile and ill. This condition subsided when the thiouracil was stopped, only to recur in a more severe form within fourteen days of resuming treatment. This picture is similar to that of Foss's patient. Barnum's and McCormick's patients became ill only during their subsequent courses of treatment. Thus in 4 out of these 5 cases the frank attack of polyarteritis developed when thiouracil compounds were given for a second or subsequent course. This fact supports the belief that polyarteritis nodosa can be due to sensitisation to various foreign substances.

SUMMARY

A woman with thyrotoxicosis developed polyarteritis nodosa while under treatment with thiouracil. The attack developed during a second course of the drug. This sequence is similar to that in three previous accounts.

I should like to thank Dr. J. E. Cates for permission to report this case and for his advice and criticism, and Prof. T. F. Hewer for the necropsy report and histological details.

PETROL PNEUMONIA

A. W. HUSBAND
M.B. Cape Town
HOUSE-PHYSICIAN

M. GELFAND
M.D. Cape Town, F.R.C.P.
PHYSICIAN

SALISBURY NATIVE HOSPITAL, SOUTHERN RHODESIA

Cope (1942) collected 6 published cases of pneumonia due to aspiration of petrol and reported one of his own. Since then few others have been published.

CASE-RECORD

An African male, aged about 22, was admitted to the Salisbury Native Hospital on Oct. 2, 1951. On the day before admission he was coming from Bindura to Salisbury by car, when the car suddenly stopped and he was instructed to blow into the petrol tank. He blew, but then stopped to inhale, and petrol immediately welled up into his mouth and out of his nose. He coughed violently and collapsed. Feeling extreme nausea he put his finger into his mouth and vomited blood mixed with bile. On admission to hospital he had persistent cough and complained of vague pains in his chest.

On examination he was not unduly distressed. His temperature was 100·5°F, he looked well, and there was no cyanosis or pallor. No sputum was produced. On auscultation of the chest tubular breathing with respiratory crepitations was audible in the right base anteriorly. Scattered rhonchi were heard over both lungs. The heart was normal. The blood-pressure was 120/86 mm. Hg.

Radiography showed a large irregular dense shadow over each lower lung field, typical of an aspiration bronchopneumonia (fig. 1).

Examination of the blood showed hæmoglobin 83%, white cells 5100 per c.mm. (neutrophils 57%, lymphocytes 41%, monocytes 2%).

Other Investigations.—The Paul-Bunnell agglutination test for glandular fever was negative. Routine urine and stool tests were negative.

Treatment and Progress.—The patient was given penicillin and sulphathiazole, and recovery was rapid. His cough persisted for two days. His pyrexia continued for about three days and then subsided gradually. Radiography some days later showed that the lung changes were rapidly clearing (fig. 2). He was discharged on Oct. 15, having completely recovered.

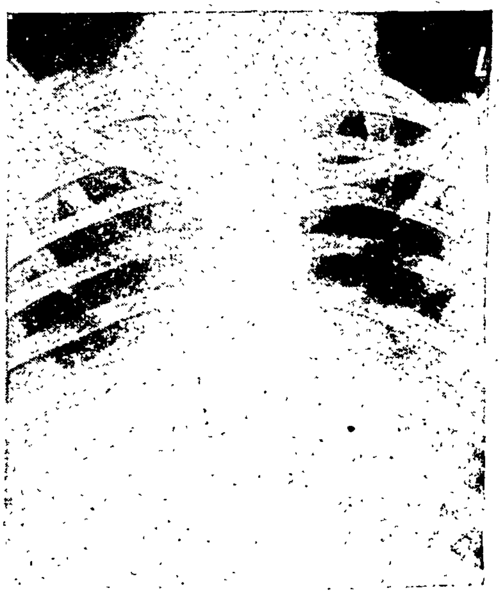

Fig. 1—Extensive bronchopneumonic lesions at both bases two days after inhalation of liquid petrol.

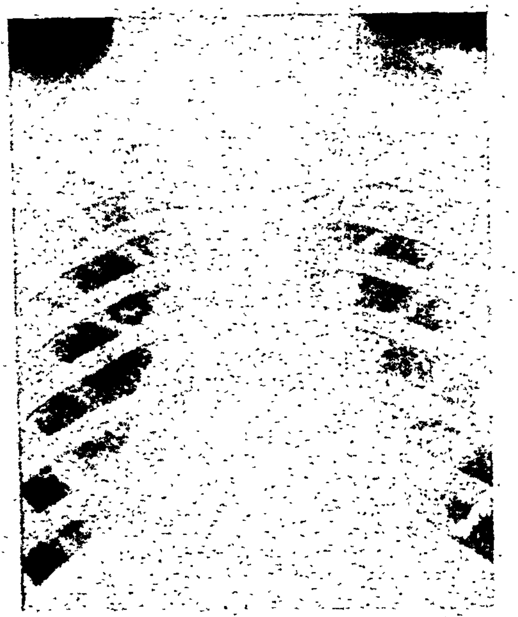

Fig. 2—Same case as fig. 1 four days later, showing rapid improvement.

COMMENTS

The effects of aspiration of liquid petrol are to be distinguished from those of aspiration of petrol vapour—e.g., in the holds of ships. The main effect of vapour seems to have been mental with schizoid and epileptiform disturbances in the foreground. Pneumonia may follow the inhalation of petrol vapour, but it is more common after the inhalation of the liquid (Rudd 1944).

Cope (1942) classifies the effects of aspiration of fluid petrol into immediate, general, and delayed. The immediate effects are due to irritation of the bronchial tree—e.g., burning pain in the œsophagus, nausea, vomiting, collapse, and cyanosis. The general effects are due to absorption of petrol into the blood-stream—e.g., transient exhilaration, drowsiness, cyanosis, and unconsciousness. The delayed effects are wandering pneumonia, hæmorrhagic pneumonia, pneumonitis, and pleural effusion. Cope declares, however, that lung signs are not necessarily proof of aspiration, because petrol in the blood-stream is largely excreted in the expired air and by irritating the lungs may produce bronchitis and coarse crepitations in the chest. He mentions three reported cases in which a pleural effusion followed the aspiration of petrol and one in which there were wandering pneumonic signs for nearly two months after the accident.

We wish to thank Dr. J. D. Addison for the photographs and Dr. R. M. Morris for permission to publish.

Preliminary Communication

MEPACRINE AND RHEUMATOID ARTHRITIS

Describing the successful use of mepacrine in the treatment of lupus erythematosus, Page[1] said that 2 of his patients also had arthritis, and that this, too, was much improved. It seemed logical therefore to try mepacrine in rheumatoid arthritis. It has now been given to 23 patients, and all but 1 are very much better. The longest period of observation is eight months, and the shortest six weeks.

Patients were selected who had had the disease for more than two years, and who showed active joint inflammation. Periarticular swelling of several joints and tenderness on pressure were present in each case, and were taken to indicate active disease. Symptoms and signs, and results of performance tests, were recorded on a chart at each examination—weekly for inpatients, and every two or three weeks for outpatients. At first no definite scheme of dosage was followed. An attempt to hasten improvement by giving larger doses at the start was abandoned in favour of repeated small doses of mepacrine (0·1 g. twice daily).

Apart from physiotherapy, 14 patients had been having salicylates only. As their skin became yellow their pain gradually eased and they needed less analgesics. Soft-tissue swellings subsided, and movement became free and more vigorous. Joints showing contracture or ankylosis, or with secondary degenerative disease, lost all signs of active inflammation. Power of grip and speed of walking gradually improved. Six to ten weeks of treatment were necessary before all signs of joint inflammation were lost.

6 patients who had been doing fairly well on cortisone were given mepacrine instead.

4 of them are now much better and almost free of pain. The 5th patient had severe psoriasis arthropathica which responded well to both A.C.T.H. and cortisone, but relapsed when treatment was stopped. Mepacrine was given instead, at first in large doses, and four months have now passed with no rash or active arthritis—an experience he has not had since 1944. The 6th patient has steadily deteriorated since cortisone was stopped, though mepacrine was tried for thirteen weeks. She is still far better than before she had cortisone, but she has been our only failure so far. Strangely enough she is the only patient with a normal erythrocyte-sedimentation rate; those of all the others have remained raised.

In 3 cases the patient had had a long course of gold without benefit, but swelling and tenderness of the joints subsided completely while they were having mepacrine.

The only serious complication was a widespread macular eruption which developed in a patient who had 0·8 g. daily for four days; this took a week to subside after mepacrine was stopped, and treatment was then resumed with smaller doses.

COMMENT

This series was quite uncontrolled, and, of course, the patients were aware that the treatment was unusual. However, spontaneous remission is unlikely to be the explanation of the improvement in every case, and we believe that mepacrine may have been the effective agent. It is far too early to be certain about this; for the course of rheumatoid arthritis is remarkably variable, and the multitude of apparently successful treatments in individual cases is notorious.

Those who wish to try mepacrine must not expect improvement for at least four weeks, even though the skin is quite yellow. Indeed, one of our patients, who has had two courses, believes that during the third week of each course there was an exacerbation. Initial large doses involve the risk of toxic complications. We can not yet say when to stop treatment.

Reviews of Books

The Advance to Social Medicine

RENÉ SAND, professor of social medicine, University of Brussels. London: Staples Press. 1952. Pp. 656. 42*s*.

Prof. René Sand, that great apostle of social medicine, has taken mankind as his field of study, and the whole world as his parish. There is no book quite like this, which skilfully condenses the histories of the medical profession, the hospital services, the history of personal hygiene, public health, social hygiene, industrial medicine, and social assistance. The last two parts are devoted to histories of the studies of man and the advent of social medicine. The expression "social medicine," he tells us, was first used in 1848 by Dr. Jules Guérin, editor of the Parisian *Gazette médicale*. Guérin appealed to the French medical profession to play a greater part in social questions:

> "Who, if not the doctor, will assess the causes of physical debility in the classes which have lately benefited by the destruction of privilege, and will find ways to make them healthier, stronger and happier? One great question is present today in all our thoughts; what will be the effects of higher wages and shorter working hours? Let us not forget the important services which doctors are called upon to render to society. At a time like this when mistrust is everywhere, *we need someone to act as intermediary between factions and* opposing interests. Truly, social medicine is the key to the burning questions of this hour of regeneration."

It is necessary to remind ourselves that this was written over one hundred years ago.

Among the international contributions to social medicine described, we can have pride in the record of this country, and particularly in its part in the great sanitary awakening of the last century. Today, when so many problems are raised by the introduction of sickness benefit services on a national scale, we may well be grateful that Professor Sand gives us a glimpse of the forces of social evolution at work, and of the many men and movements which have contributed to the flowering of the idea and practice of social medicine today.

Early Care of the Seriously Wounded Man

HENRY K. BEECHER, M.D., chief, department of anæsthesia, Massachusetts General Hospital, Boston, Massachusetts. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 32. 6*s*.

THOUGH written by an anæsthetist, this little book is full of good advice about the general surgical care of seriously wounded people. Casualty officers in busy hospitals, as well as members of field ambulances, will find here good dogmatic advice. Professor Beecher believes in speedy evacuation to hospital where definitive surgery can be done. In describing early resuscitation and care, he rightly emphasises the harmful effects of morphine when used improperly, and he gives a valuable list of contra-indications to its use. As would be expected, the section on anæsthesia is well done, and he has clearly mastered all the lessons learnt in recent battlefields. Not the least of these is that the dose of any anæsthetic must be graded according to the condition of the patient. Professor Beecher is to be congratulated on a first-rate pocket book, and its reasonable price puts it within reach of everyone who has to treat injured people.

Control of Communicable Diseases

HUGH PAUL, M.D., D.P.H., medical officer of health for Smethwick. London: Harvey & Blythe. 1952. Pp. 526. 55*s*.

MANY books deal with the clinical aspects of infectious or communicable diseases but few describe their control. Although not everyone will agree with Dr. Paul's views or conclusions, his book will be read with profit by medical and lay workers interested in preventive medicine.

Dr. Paul includes as communicable diseases war (*facile princeps*), cancer, psychosomatic disorders, and accidents in the home and on the road. The term "communicable" is more usually reserved for diseases caused by the invasion of susceptible hosts by more or less readily transmissible parasites. This idiosyncrasy apart, he has compiled a valuable and readable account of the history, demography, and epidemiology of many major and minor, endemic and exotic, infectious diseases and of the available means of controlling them. When a single author covers so much ground inequalities are to be expected. The chapters dealing with diseases of which Dr. Paul has had long personal experience are unexceptionable, but some of the accounts of exotic fevers are not well arranged and contain inaccuracies. But this criticism does not appreciably detract from the usefulness of the work especially for the English reader, who will find an excellent chapter on smallpox, the chief exotic disease he is likely to meet. The accounts of the other major communicable diseases, notably tuberculosis and diseases associated with food and water, are also first class. An informative chapter on the hygiene of food establishments is contributed by Mr. J. H. Wright, chief sanitary inspector of Smethwick.

Urological Pathology

PETER A. HERBUT, M.D. London: Henry Kimpton. 1952. Pp. 1222. In two volumes. Price £8 10*s*. the set.

THE title of this book scarcely does justice to its contents, for besides describing fully the pathology of the genito-urinary system it gives a fairly detailed account of the embryology and anatomy of each organ and a useful summary of the clinical manifestations, prognosis, and treatment of each disease. The illustrations are well chosen and well produced. A long classified list of references is printed at the end of each chapter. Since "Herbut's Urological Pathology" is likely to take its place amongst standard works of reference, we wish, for the sake of younger urologists, that it were not so expensive.

Color Atlas of Morphologic Hematology

GENEVA A. DALAND, B.S., chief laboratory assistant in hematology, Thorndike Memorial Laboratory, Boston, U.S.A.; edited by THOMAS HALE HAM, M.D., assistant professor of medicine, Harvard Medical School. Cambridge, Massachusetts: Harvard University Press. London: Oxford University Press. 1951. Pp. 74. 32*s*. 6*d*.

THIS atlas is not a complete guide to the subject set out in the title; the foreword tells us that it is "a guide for reference in the study of films of peripheral blood stained with Wright's stain," and it can be said that within these limits it fulfils its task very well.

An atlas stands or falls by its colour plates; these are by Etta Piotti, an expert in water-colour representation of blood cells, and are reasonably clear; but nuclear detail is often not adequately defined. Moreover, registration of the different blocks is not always perfect, so there is some overlapping of colours. There are 14 plates; one shows the red-cell series, one the various leucocytes, and most of the rest have two fields representing composite pictures of the peripheral blood in various diseases. One plate has only a single field, giving an admirable picture of the changes in Mediterranean anæmia; the arrangement of line diagram keys on the page opposite to this plate is especially good. The developmental histories of the blood-cell types are simply outlined in black-and-white diagrams, and the text is adequate though undistinguished. It seems from the frequent cross-references that the atlas was designed to be used in conjunction with Dr. Ham's *Syllabus of Laboratory Examinations in Clinical Diagnosis*.

The choice of Wright's stain reduces the usefulness of the work because this technique is little used outside the United States, and even there many prefer the Jenner-Giemsa combination. Laboratories in Britain still often use Leishman's stain, and good atlases representing the appearances of peripheral blood with both these stains are available. The book is beautifully produced, and its very reasonable price is made possible by a grant from the Massachusetts division of the American Cancer Society.

Il Cancro (Verona: Mondadori. 1951. Pp. 156. L.250).—Dr. Mario Musella, of Naples, has written a popular account of cancer designed to induce patients to come for treatment as soon as possible. He touches on almost every aspect of the disease and has produced a very readable story, to which Prof. Hans R. Schinz, of Zürich, contributes a preface.

THE LANCET

LONDON: SATURDAY, AUGUST 16, 1952

War on Want

IN any society extremes of wealth and poverty are morally wrong, economically unsound, and politically inexpedient. This is a thesis acceptable to almost all thinking men in Great Britain, though we dispute heatedly about the ways and means of alleviating poverty and about the necessity for restricting individual wealth. In recent years, together with other countries bordering on the North Sea, we have gone a long way to prevent poverty, and its associated moral, economic, and political evils, in our own countries; and we are therefore apt to be blind to the fact that, in the world at large, poverty is probably increasing. The fifth annual report of the Food and Agriculture Organisation [1] showed that in most countries the supplies of food and clothing do not even suffice to keep up pre-war low standards, and except in a few favoured countries the amounts of fuel and power available do little to mitigate the toils of bodily labour or the severities of climate. Few of us are properly aware that the lack of these basic essentials in so many countries leads inevitably to international chaos. The first essential in the struggle for a good life is to reduce poverty, especially as it exists in South-East Asia, in most of Africa, and in many parts of Latin America. Unless this can be achieved, our domestic problems must in the end be swamped in international disorder.

A pamphlet lately issued by the Association for World Peace [2] gives a well-documented and sober account of world poverty and the ways in which governments are trying to introduce scientific techniques to the technically backward countries. It begins by refuting the arguments of the "isolationists" who would seek salvation each for his own country. That the average income per head in South-East Asia is the equivalent of $55 a year and in the United States is $1453 represents a maldistribution of wealth which, if we regard the world as a whole, is morally unjustifiable as well as economically disastrous. Such poverty and wealth cannot exist in equilibrium side by side, and war will be an inevitable consequence of failure to meet the basic needs of a large part of the human race. A later chapter reviews the British Commonwealth's attempts, integrated within the Colombo Plan,[3] to find the technical skill and capital needed to develop Commonwealth countries in South-East Asia. But Asian opinion is quoted as being apprehensive and even cynical about the progress of the plan: the efforts of individual countries within the scheme are not being matched by Commonwealth effort: "in the Asia of today, people are sick of paper plans and promises and are clamouring for results. . . ." From this we turn to the many United Nations organisations which are endeavouring to relieve world poverty. Though the specialised agencies are, in general, doing excellent work in their particular fields, such as education, health, and land development, they often lack coördination. Partly because the people in the privileged countries lack a sense of urgency, there is no really adequate world organisation for getting a comprehensive programme carried out, and the Association for World Peace therefore presses for a new international development authority, which would have the means and the power to promote the economic and social advancement of underdeveloped areas. In this criticism of the piecemeal nature of much of the work of the United Nations there is much truth. But the energy necessary for a bolder and more coördinated attack can come only from a public enthusiasm based on accurate knowledge. Here the pamphlet is invaluable. Concise, factual, and authoritative, it can be recommended not only to individual readers but also to study groups.

In this country our task is to provide a share of the technical skill much needed for development (not a little of which is medical), and to give this skill the backing of public opinion and the necessary means.

Infantile Gastro-enteritis

GASTRO-ENTERITIS is still an important cause of death in infancy, for it is responsible for about a twelfth of all deaths in this age-group. Improved living conditions, more child-welfare clinics, and better treatment have helped to reduce the number of deaths fairly steadily since the war. But our control of what should be a preventable disease will not be complete until more is known about its cause and the reasons for its spread. In 1947 4606 deaths (5·2 per 1000 live births) were attributed to diarrhœa, whereas in 1949 the figure was 1963 (a rate of 2·7). Reports from various parts of the country suggest that there were many outbreaks in 1947, but few in 1949, so that the rate may not be maintained at this low level in the future. The disease is more prevalent in densely populated areas; the 1947 infant-mortality rates for county boroughs and rural districts were 8·7 and 3·1 per 1000 live births respectively, and the difference was still to be seen in 1949, when the corresponding rates were 2·7 and 1·9. It commonly breaks out in institutions where babies are gathered together under good hygienic conditions, suggesting that overcrowding of a susceptible population may be the most important cause of its spread. No simple classification of the disease is possible, for several unrelated agents may irritate the baby's gastro-intestinal tract. In spite of this difficulty it is clear that the disease may affect babies alone or babies and adults at the same time, and there is reason to believe that these are two ætiologically distinct conditions.

Many attempts have been made to identify a specific infective agent, and a number of these have been studied recently. As a result of work in America it is now accepted that some acute diarrhœas in adults are due to virus infection. KEITEL [1] investigated an outbreak affecting both adults and babies, and he found that in many cases the babies' sera gave raised titres to cold agglutinins and to Streptococcus M.G.; both these findings are suggestive of virus infection, but no attempt to isolate one

---

1. Keitel, H. G. *J. infect. Dis.* 1950, 86, 219.

was made. Light and Hodes[2] believed that they were able to isolate a virus from some outbreaks affecting babies only, but this has not yet been confirmed. Gale[3] showed that some strains of *Strep. fæcalis* produced an enzyme that changes tyrosine to tyramine, which gives rise to diarrhœa in young rats; he suggested that such organisms might cause diarrhœa in babies. Sharpe[4] investigated streptococci from outbreaks of infantile gastro-enteritis and found that the number of *Strep. fæcalis* isolated from sick babies and their contacts was greater than from healthy non-contact babies. On the other hand, the specific enzyme activity of streptococci from both groups of babies was similar, and there was no evidence that these organisms were related to the disease. Strains of non-hæmolytic streptococci are known to cause food-poisoning, and, before finally dismissing this group of organisms, more information is needed on their incidence, particularly in relation to the mild outbreaks.

Infantile diarrhœa, obviously infectious, occurs in outbreaks, some of which are due to organisms of the salmonella and shigella groups; but from others no causal agent can be isolated. Organisms of the salmonella group cause a larger number of deaths in infancy than in any other age-group, suggesting that the baby is particularly susceptible. In spite of this, outbreaks occur in which babies excrete a salmonella organism without showing any clinical symptoms. In the ward outbreak described by Hinden et al.,[5] *Salmonella brancaster* was isolated from 10 babies, of whom 2, aged thirteen months, remained healthy and 4 others, including 2 only about four weeks old, were classified as mild. Although this age-group is particularly susceptible, the healthy-carrier rate is often much higher in other outbreaks. This must be borne in mind in assessing the importance of recent work on certain serological types of *Bact. coli* as a possible cause of gastro-enteritis. On numerous occasions *Bact. coli* type 0·111 (D433) and type 0·55 (β) have been isolated from sporadic cases and from outbreaks in institutions in all parts of the world. These organisms have rarely been isolated from healthy babies who have had no contact with the disease. Shanks and Studzinski[6] report that 39 of 158 babies with gastro-enteritis were excreting type 0·111, and they also state that there was no outbreak of gastro-enteritis in the locality during the period of investigation. This figure may be compared with that of Giles and Sangster[7] who found that 96 of 159 patients excreted type 0·111 during an epidemic mainly confined to an overcrowded part of Aberdeen. Type 0·111 has also been reported as important in some institutional outbreaks[8]; it was recovered from all babies involved in four outbreaks but it was absent in a fifth, and it was not isolated from 175 healthy babies.

On this evidence it must be accepted that *Bact. coli* type 0·111 is an organism which occurs in epidemics in the infant population both at large and in institutions. Experiments on the pathogenicity of type 0·111 have been carried out in the U.S.A. where Neter and Shumway[9] have shown that the feeding of this organism to a baby was followed by acute gastro-enteritis. Ferguson and June[10] carried out a carefully controlled feeding experiment, using varying doses of three type 0·111 strains isolated from sick babies, and an untypable strain of *Bact. coli* from a healthy baby. After large doses of 0·111, young adult male volunteers had diarrhœa and vomiting, but they had no symptoms after similar doses of the control strain; in addition, agglutinins to 0·111 developed in the patients' serum after recovery. In a carefully planned investigation of streptomycin treatment, Alexander et al.[11] found that *Bact. coli* 0·111 or 0·55 were more commonly isolated from those patients classified as severely ill on admission—an observation which agreed with the findings of Holzel et al.[12] and Shanks and Studzinski.[6] But Young et al.[13] found type 0·111 to be evenly distributed among severe and mild cases. This difference may be explained by the gradual replacement of one epidemic type by another, as has happened in Aberdeen, where type 0·111 was prevalent in 1947 and type 0·55 in 1949; there are very few cases in Aberdeen at present, and no identifiable type of *Bact. coli* can be isolated from them. No adults were affected in any of these outbreaks.

Rogers[14] has shown that type 0·111 can be isolated from the furniture, towels, and other materials which have been in contact with an infected patient, but as yet there is nothing to suggest what is the most important means of spread. The organism is rarely, if ever, isolated from milk feeds, but it has been isolated from teats and fluid in which teats are kept, and from nurses' hands. If the usual portal of entry is the mouth, special care in sterilising bottles, teats, and other things put into the baby's mouth should help to prevent the disease. In spite of the strict technique adopted in many institutions, the disease still appears in epidemic form; this may be the result of inadequate methods, or it may indicate another mode of spread. In Sweden it is believed that droplet infection may be important, for positive cultures have been obtained from the nasopharynx of babies immediately before the onset of clinical disease; but workers in this country have failed to confirm this finding. By analogy with other intestinal infections, one would expect the introduction of the organism into the baby's mouth to be the commonest way in which the disease may spread. It has been shown that the admission to a ward of a patient who is excreting type 0·111 results in a wide dispersal of the organism in the environment. The baby's napkin may be compared to a dressing on infected burns, which can load the air with organisms and so spread the infection to other patients in the ward.

Stevenson[15] isolated *Bact. coli* 0·111 from adults with diarrhœa, all of whom were suffering from some other debilitating illness. He also found a carrier rate of 1 in about 200 among healthy adults in

Glasgow.[16] It is possible that these types of *Bact. coli* may behave in the same way as some serological types of pneumococcus which, though usually present in a healthy population, may occasionally cause epidemic disease.

Treatment with each new antibiotic in turn has been tried, and each one has had its supporters. It is now accepted that penicillin is only of value in specific parenteral infections. Alexander et al.[11] have shown conclusively that streptomycin is useless in infantile gastro-enteritis. Good results have been reported with chloramphenicol,[17–19] but others have found it of little help.[6] In a disease which is certainly caused by a number of different agents it is probable that the treatment will not be correctly assessed until the causes can be diagnosed.

To sum up, there are a number of agents which cause gastro-enteritis in babies, and some of them are undoubtedly infectious. As yet there is no proof that a virus is the cause, although work on adults suggests that this may be so, particularly in outbreaks affecting both adults and babies. Gastroenteritis may follow feeding experiments with *Bact. coli* type 0·111 in both babies and adults; and this type has been isolated in infantile diarrhœa in all parts of the world, and in diarrhœa in adults with debilitating disease. There is now good evidence that this type of *Bact. coli* may cause infantile gastroenteritis both as a sporadic and an epidemic disease.

Neurology Advances

The first two or three streaks of paint on a canvas convey very little, but as the brush strokes multiply and gain in complexity the picture paradoxically grows simpler. Neurologists, working hand in glove with the biochemists and neurophysiologists, are watching the appearance of some remarkable new landscapes in their field. In the Shattuck lecture[20] for 1952, Prof. D. E. Denny-Brown chose some of these to illustrate his theses that neurologists must keep the catholic outlook of the general physician, and that physicians in other branches of medicine can look to neurologists for practical help with their problems.

As an example of the kind of question an active neurological department can help to answer he mentioned the relation between liver and brain. In 1912 Kinnier Wilson established the association, in the disease named after him, of progressive lenticular degeneration with cirrhosis of the liver, and demonstrated the relation between extrapyramidal symptoms and disease of the basal ganglia. Later observers noted pigmentation of the cornea (the Kayser-Fleischer ring) which is pathognomonic of the syndrome, though not always present. The degeneration in the brain may go on to cavitation, but in some forms of the disease it is replaced by a pseudosclerosis—the condition studied between 1883 and 1898 by Alzheimer and Westphal, and long thought to be a separate entity. These different pathological aspects turn out to be related to different rates of evolution of the disease. Patients have also been shown to have amino-aciduria, huge deposits of metallic copper in the brain and liver, and a high urinary output of copper.[21] The neurological signs, usually starting with tremor of the limbs and sometimes athetosis, go on to rigidity, contractures, dysarthria, a parkinsonian facies, emotional lability, and mental deterioration; but lately it has been found that treatment with dimercaprol (Bal) mobilises some of the copper deposits, and—provided cavitation has not developed—ultimately causes most of the neurological symptoms to disappear.[22] The amino-aciduria, however, persists. The neurological symptoms thus seem to be caused by the deposits of copper; but the origins of the disease are in some other system. It was thought that the cirrhosis might interfere with the excretion of copper in the bile; but the biliary output of copper has been measured in several cases, and found to be within normal limits. Attention has therefore turned to the nature of the hepatic cirrhosis. It is of a coarsely nodular type, and during its development the patient experiences pyrexial attacks with slight jaundice, believed to be recurrent episodes of toxic liver disease, but without inflammation. We have no direct clue as yet, Denny-Brown says, to the mechanism of the disorder, but there is some suggestive collateral evidence.

> Thus in hæmochromatosis (like Wilson's disease, a familial disorder) an ordinary multilobular cirrhosis of the liver is associated with the deposition of large quantities of iron-containing pigment in different parts of the body. The deposits in the pancreas engender diabetes; and though there are no specific neurological signs, the patients show a characteristic drowsiness and torpor which is independent of their diabetes. Again, in chronic manganese poisoning, cirrhosis of the liver, tremor of the hands, and dysarthria develop, and here the metal is the cause of both the cirrhosis and the nervous symptoms. Other studies have shown that copper, too, can cause cirrhosis.

Wilson's disease thus begins to appear as a disorder in the metabolism of the heavy metallic ion of copper. Moreover these comparable conditions suggest that the trouble is not a disorder of the enzymes of which copper is normally a part, but a displacement of some other physiologically important ion by copper.

The study of the liver in Wilson's disease has clearly taken neurologists far into the realm of general medicine; and some of the findings in the brain lead in the same direction. The cavities found in the rapidly progressive forms of the disease are in the basal ganglia and dentate nuclei, and sometimes in the frontal lobes; otherwise the brain shows only pigmentation and a diffuse alteration in the glia—notably enlargement and proliferation of astrocytes. But similar enlargement of the astrocytes has been found in cases of chronic biliary obstruction, ordinary portal cirrhosis associated with "senile" chorea, and recurrent hepatic coma. Denny-Brown therefore postulates a primary metabolic disturbance of cerebral glia, parallel to the primary metabolic disorder of cerebral vascular epithelium in Wernicke's encephalopathy; and this, he says, opens "an extraordinary vista of possibilities in neurology."

We are fairly sure, for instance, that parkinsonism, Huntington's chorea, presenile psychosis, and the familial ataxias are not related to a disorder of *metallic*

metabolism; but we are equally sure that some cumulative metabolic process underlies these disorders, for "in each of such diseases a progressive cell change documents the gradual failure of specific metabolic processes without gross anatomic lesions." This is very different from the old concept of abiotrophy; and the slightness of the anatomical damage in relation to symptoms suggests that reversal may be possible once we understand the chemistry.

Recent experience of young people in the first stages of Wilson's disease has impressed DENNY-BROWN strongly with the importance, as an early sign, of "small lapses and irregularities of movement, of the type characteristic of Sydenham's chorea." In Wilson's disease these signs clear rapidly with dimercaprol; and they give us good reason for believing that Sydenham's chorea is itself a toxic symptom, produced by some metabolic mechanism.

Another new scene in neurology is opening from the well-explored canyon of cerebrovascular disease. MONIZ, in 1937, described recurrent cerebral attacks due to carotid occlusion; but this thesis only gained recognition when carotid arteriography came into general use. It was then seen that patients with a history of repeated episodes of weakness of the same limb, with or without aphasia, were suffering from the effects of occlusion of the carotid on the opposite side of the body to the paresis. These symptoms are therefore due, not to vasospasm as we used to think, but to insufficiency of the circulation in the circle of Willis, and resultant ischæmia in parts of the brain not well supplied with collateral circulation. Moreover the episodes are provoked not by a rise but by a *fall* in the systemic blood-pressure; and a severe fall in the systolic pressure, such as occurs in syncope or with intestinal hæmorrhage, may lead to necrosis of a large part of the area supplied by the middle cerebral artery. In an interesting variant of the disorder, reduced flow in the ophthalmic artery is responsible for recurrent attacks of blindness in the eye on the side of the carotid occlusion. But sometimes the patient will develop a collateral circulation for the ophthalmic artery through the external carotid system, by way of the branches of the ciliary and meningeal arteries. This has the curious effect of reversing the flow in the ophthalmic artery, with the result that the internal carotid can be filled from the external carotid; and this explains why the attacks of blindness sometimes persist for a time and then disappear.

The cause of the internal carotid occlusion is usually arteriosclerosis with atheroma, and hence is usually seen in patients of 50–60, though it may appear in young people: DENNY-BROWN has seen it in a patient of 26. The common story is that a patient with long-standing arterial disease, who has had an unexplained episode of transient paralysis in the right arm with aphasia some years before, starts to waken from sleep with fleeting attacks of weakness of the right limbs and difficulty with speech. The important thing to keep in mind is that he needs not a vasodilator drug but a stiff whisky. Anything that *lowers* his blood-pressure still further is likely to provoke a severe hemiparesis. Apart from alcohol by mouth, inhalation of air containing 6% of carbon dioxide seems to be the most effective immediate procedure. But it is of course essential to get the diagnosis right. Carotid occlusion can be proved by arteriography, but DENNY-BROWN does not advise this in old people, whose atheromatous vessels are only too likely to thrombose. Instead, two clinical tests may be tried: the fundus on the side of the suspected lesion is watched while the opposite carotid is compressed, or while light pressure is exerted on the globe of the eye with the finger. If the retinal vessels are being filled from the opposite carotid these tests will cause them to narrow. But the tests are positive in only about half the cases, probably because in the others, collaterals from the external carotid have already developed. Compression of the suspected carotid will reproduce the symptoms in 30 seconds, also in about half the cases. But the surest clue to the diagnosis is in the history of repeated episodes of transient paralysis in the same limb.

Nicety of diagnosis was again his theme in discussing raised intracranial pressure; for here good judgment makes the difference between life and death for the patient. Brain tumours, we used to be taught, produce their symptoms by increasing intracranial pressure; but in fact they also act by distorting the anatomical relations within the skull. If the high pressure continues, the retinal veins are compressed and papillœdema develops, to be followed, unless relieved, by blindness. An expanding lesion in the skull causes herniation, first of the midbrain and temporal lobe through the tentorial opening, and then of the tonsils of the cerebellum into the foramen magnum. Herniation of the first type produces dilatation of the pupils, stupor, and a decerebrate state; herniation of the second type causes periodic headache, vomiting, slowing of the pulse, drowsiness, and finally respiratory failure. Either will eventually obstruct the circulation of the cerebrospinal fluid and cause a secondary rise of intracranial pressure. The important point is that lumbar puncture can only increase the herniation in cases with intracranial lesions; and that the signs of herniation are periodic bursting headache, dilatation of one or both pupils, vomiting, and resistance to passive flexion of the neck. In the absence of these signs, on the other hand, papillœdema must always be studied by examination of the cerebrospinal fluid obtained by lumbar puncture and cautious measurement of its pressure. Thus the mild degree of papillœdema produced by hypertensive heart-failure associated with high venous pressure should be treated by lumbar puncture; and so should the greatly raised pressure seen in some cases of otitis media with lateral sinus thrombosis, where the venous drainage of the sagittal sinus has become blocked by the spread of thrombosis. Both these conditions can be relieved, and the sight of the patient saved, by repeated cautious lumbar puncture. Again, there is a type of peripheral neuritis, recently observed, in which the cerebrospinal fluid clots spontaneously and plugs the pacchionian bodies, thus obstructing its own drainage. In time the blocks will be canalised afresh, but while this is happening lumbar puncture drainage is needed to save the patient's life and sight.

The neurologist, then (and even more the house-physician and general practitioner), must have a very clear idea of what he is about when he reaches for the lumbar-puncture needle, for, as DENNY-BROWN implies, the dangers of an ill-judged lumbar puncture which produces blockage of the foramen magnum may be as disastrous for the patient as loss of vision resulting from the doctor's inability to exclude a tumour. It is no use attempting to play for safety: in this situation masterly inactivity will not serve instead of accurate diagnosis.

Annotations

CRIMINAL STATISTICS

INDICTABLE offences known to the police amounted to 524,506 in 1951—almost twice the number of such offences in 1938.[1] Moreover this figure exceeds by nearly 2000 that for 1948, the former peak year. The number of people found guilty of offences of all kinds was 723,320. It must, of course, be remembered that more than half these offence were non-indictable traffic offences, failures to take out dog- or car-licences, breach of local regulations, and the like; only 3929 (0·5%) had committed acts of violence. But it is not the proportion of one type of crime, or even the incidence of a given type of criminal in the population which must engage us so much as the fact that on the whole crime is on the increase in our country. It is natural to ask what types of crimes are rising, and in which age-groups of the population.

The Criminal Statistics for 1951 show very large increases in larcenies of different kinds—from some 56,000 offences in 1938 to over 87,000 in 1951; but there are some odd exceptions to the general picture. Thus embezzlement is rather less popular than it was in 1938, though it has gone up since 1949; larcenies of horses, bicycles, and motor vehicles have been almost stationary since before the war, and larceny from automatic machines and meters was more than three times commoner in 1938 than it is now—though it has been picking up a little during the last few years. The offences which swell the figures are larceny by servants, from the person, in the house, of post letters, and from unattended vehicles, shops and stalls, and aggravated larcenies—lazy, petty thieving in the main, probably attempted without much risk, and for only small gains. The picture, in fact, seems rather one of rapidly falling standards than of growing malice. The change for the worse is very noticeable in the younger age-groups. Children over 8 and under 17 found guilty of larceny have risen from some 19,000 in 1938 to over 30,000 in 1951, whereas the figure for those aged 17–21 has remained almost steady in the neighbourhood of 8000–9000. Indeed, of the 87,201 people found guilty of larceny in 1951, 35% were under 17. A somewhat similar picture appears in the figures for breaking and entering: children under 17 composed 57% of those found guilty.

It is hard to assess what factors are at work in producing the increase in crimes of violence. The numbers found guilty have risen steadily, from 1583 in 1938 to 3929 in 1951. Every age-group has been affected, but in the group aged 21–30 the figure has remained in the region of 1500 for the last three years, while in other age-groups, and especially among those under 17, it has been rising. Nevertheless, those under 17 are responsible for only 9% of these crimes, while those aged 17–21 are responsible for 12%, and those aged 21–30 for 40%. Different types of violent crime are not all increasing at the same rate: some indeed are less common than they were in 1938. Those found guilty of murder, always an exceptional crime, have ranged between 20 and 40; and those who attempted murder have fluctuated between 15 and 40. On the other hand, those guilty of threats, conspiracy, and incitement to murder have risen from 9 to 23, and those causing manslaughter from 45 to 71. Those guilty of wounding and other acts endangering life (felonies) have trebled since 1938, but on the other hand their numbers fell off from 385 in 1950 to 354 in 1951. Convictions for malicious wounding and like offences (misdemeanours) form the largest group, and have gone up steadily from 1195 in 1938 to 3169 in 1951. Over the same period convictions for assault have risen from 39 to 103, but fell a little between 1950 and 1951. There were 30 convictions for cruelty or neglect of children, as against 12 in 1938; but both criminal abortion and concealment of birth are on the decline and child stealing does not seem to have been a popular pursuit in this country for many years. Endangering the life of railway passengers (it would be interesting to know exactly how) led to 52 convictions in 1951 as against only 9 in 1938.

On the whole there is evidence of a growing bent for threats, spitefulness, carelessness, and irresponsibility, among our people, as well as some growth of villainy. To this must be added an increase in sexual offences, which doubled between 1938 and 1951. The picture suggests a restless unhappy spirit which no doubt owes something to current history, but more, perhaps, to poor training in social living.

HOSPITAL COST ACCOUNTING

THE Hospital Costing Returns for 1950–51[1] were compiled according to a system proposed in an interim report of the costing subcommittee of the Committee of Regional Board Treasurers. This committee has now prepared a second report[2] which suggests how the "subjective" analysis set out in their interim report may be supplemented by an "objective" analysis of the expenditure of the larger general hospitals with special departments for inpatients and outpatients.

The need for a better basis of comparison is obvious, but it is perhaps a pity that the committee should feel "that the immediate purpose of this objective analysis should be to separate the cost of treating in-patients from the cost of treating out-patients" and that the production of truly comparative costs may perhaps be the most important result of any costing system. Surely the first object of accounting should be to provide the administrator with the information he and his departmental heads require for efficient management? If uniform costing emerges as a by-product of a process of management accounting, then indeed the hospital service will benefit. The committee has attempted to meet both needs, but its chief aim seems to have been to provide figures which will be of interest to the Ministry of Health and the general public rather than to hospital administrators.

The committee considers that the present subjective analysis of expenditure required under Ministry of Health regulations should remain and that the objective analysis should be produced by an additional accounting process, which must in the interests of economy be as simple as possible. Surely it would be simpler to substitute the objective analysis for the subjective analysis as the basis of hospital accounting. Moreover, unless this is done and hospital estimates are built up departmentally, the full benefits of functional costing will never be felt, and the cost of costing may then indeed be an extravagance.

The committee's proposals must be examined from two points of view. One is the need to provide the Ministry with yardsticks by which it may allocate national funds to regional hospital boards and compute comparative costs for publication. But information is also needed for efficient management and control at hospital level, and, unless costing is integrated in a system of budgetary control, it will not be of full use for administrative purposes.

[1] See *Lancet*, 1952, i, 1243.

[2] Copies of the report are in the hands of the treasurers of the regional hospital boards.

Appendix C to the report sets out the forms of cost statements proposed. The cost summaries for inpatients and outpatients show in one total the proportion of direct and indirect expenditure allocated to each. To this is added the relative proportion of the expenditure on special departments such as radiology, pathology, and physiotherapy. In a subsidiary statement a full subjective analysis is given of the direct expenditure and a departmental analysis of the indirect expenditure. The allocation of expenditure between the cost of treatment of inpatients and outpatients is made on varying arbitrary bases, but this is inevitable. Neither of these statements alone, however, would give a comprehensive comparison and together they are far too detailed. But they do provide all the necessary information from which a statement of inpatient and outpatient cost, showing the more important items of expenditure, could be evolved.

These proposed forms would give a much better basis for inter-hospital comparison than the present costing return, but certain anomalies would still remain. For example, unless the cost of catering is treated as a separate department and the cost of patients' meals only is shown as direct expenditure under inpatients, there will still appear apparently inexplicable differences, and the reason for them will have to be sought by reference to another section of the cost statements. A full departmental accounting system would avoid these difficulties. Moreover, this comparison is to be restricted to the larger multi-purpose hospitals and the basis of comparison for all other hospitals is thus not improved.

The bulk of the report is a cost-accounting manual for hospitals dealing with the details of the proposed system —the allocation of expenditure, the cost units to be used, and the bases on which expenditure is allocated between inpatients and outpatients. Clearly much valuable work and thought have been given to this report, and it will be of interest to consider these proposals, made within the framework of the Ministry's regulations, alongside the forthcoming reports on the experiments on hospital costing carried out by the King's Fund and the Nuffield Provincial Hospitals Trust.

PREDICTING ADULT HEIGHT

By comparing skeletal age, as assessed by X-ray examination of the hand, with chronological age and height, Bayley,[1] was able to predict the height of the fully grown adult. Bayley and Pinneau[2] have now brought their tables up to date in the light of new data on skeletal age.[3] They show that there is a high correlation between skeletal age, as taken from Greulich and Pyle's atlas, and the proportion of final adult stature that has been reached when the X-ray film is taken. They suggest that this shows the close relation between growth in size and skeletal maturation, as well as the possibility of predicting the adult height.

Growth is a dynamic and highly complex process influenced by nutrition, illness, hormonal changes, and hereditary traits, to name only a few of the factors involved. To make an assessment of skeletal maturity at one point during this process, and then to predict the mature height for a particular child, seems an uncertain business. The results may be reliable enough in a homogeneous sample of children, but we must also consider the children whose growth is retarded or advanced at the time of the assessment. It appears that "supplementary" tables should be used in such cases.

Nevertheless this work is of great interest; it will attract the attention not only of geneticists but of those engaged in studies of longitudinal growth. The first set of results from such a study in the British Isles has just been published.[4] Detailed and varied measurements were made of the same sixty-six boys and sixty-six girls at the ages of 3 days, 1 year, 2, 3, 4, and 5 years. This work, when combined with that of Bayley and Pinneau and others, may help in the "somatotyping" of children into various groups according to build; it may then be possible to predict the adult somatotype from the childhood assessment. Perhaps adult physique is determined at a very early stage in the development of the embryo; perhaps the predominant influence comes later.

FOOT-AND-MOUTH DISEASE AND BIRDS

For nearly forty years birds have been suspected of introducing foot-and-mouth disease. Mettam[1] suggested it in connection with an outbreak of this disease in Ireland in 1912. Stockman and Garnett[2] tried to link primary outbreaks in England with the immigration of birds from the Continent. Eccles[3] succeeded, with difficulty, in infecting wild starlings and found that, after the ingestion of infected material, they excreted the virus in their droppings for 10–26 hours, and that, when their feet and feathers were contaminated, the virus could be recovered up to a maximum of 91 hours later. Eccles also transmitted foot-and-mouth disease from an infected starling to a healthy beast. There is no evidence that the ingested virus multiplies in the birds, and the birds are not susceptible to the disease; hence they can but carry the virus mechanically.

A big step forward has been taken by Wilson and Matheson,[4] who analyse the migration of birds to, from, and through the British Isles. The man in the street knows vaguely that some birds, such as swallows and nightingales, come north for the summer and go south in autumn, but it is not generally realised what enormous hordes of different species of birds, notably starlings, come to the British Isles from the Baltic area in autumn and spend the winter here. It is, of course, from this direction that new outbreaks of foot-and-mouth disease in the south-east of England must be introduced. Wilson and Matheson show that, between April 1, 1938, and Oct. 31, 1950, there were 365 primary outbreaks in Great Britain, and that, of these, 223 were in pigs, 134 in cattle, and 8 in sheep. Of the 142 in cattle and sheep, 50 might have been due to contamination by pig-swill, and 49 of the remaining 92 were concentrated in the eight coastal counties (from Lincolnshire to Dorsetshire) nearest to the Continent, and these counties contained only a seventh of the live stock of the country. On the other hand, the number of outbreaks due to swill in these coastal counties was only a sixth of those in the rest of the country. These facts proved that in most of the primary outbreaks the proximity of the Continent was an important factor, birds being the obvious suspects when swill was not responsible.

Wilson and Matheson further point out that, since the numbers of immigrant starlings do not fluctuate much from year to year, the primary outbreaks of foot-and-mouth disease in England should, if these birds are the vehicles of transmission, be definitely correlated with the outbreaks in the neighbouring parts of the Continent: Holland, Belgium, and Pas de Calais. They prove that not only is this so but also the danger to England is greatest, and in fact only exists, when foot-and-mouth disease has attained certain proportions in the coastal provinces of East and West Flanders in Belgium, and of South Holland, North Brabant, and Sealand in Holland, just where most of the starlings congregate before crossing to England, where the primary outbreaks of foot-and-mouth disease are shown to hug the coast

to a conspicuous degree. The multiplicity of types of the virus[5] facilitates the establishment of this correlation.

Finally, the starlings migrate from the Continent to England in the daytime in a season which provides ten hours' daylight; and, even if they cross by the longest sea trip—i.e., from Holland to Yorkshire—they have ample time to contact beasts in both countries on the same day.

REMUNERATION OF GENERAL PRACTITIONERS

On July 28, before rising for the recess, Parliament passed without debate the outstanding votes of the Civil Estimates which included provision for the Danckwerts award.[6] Before the new rates of pay can be introduced, the modifications in the organisation of general practice recommended by the Working Party[7] must be put into effect. This pre-holiday legislation has left the way clear for the Ministry of Health during the summer months to start to make the necessary administrative changes. Apparently unmoved by the doubts which assail Mr. H. A. Marquand,[8] the Ministry of Health announce that they hope to make the changeover on April 1, 1953.

As a first step they have asked the Medical Practices Committee[9] to reclassify the "practice areas" into three categories instead of four. The new categories will be:

designated, where an application for admission to the medical list will be granted automatically by the Medical Practices Committee and where, on admission, a doctor who is genuinely setting up a single-handed practice will be entitled to receive an initial practice allowance;

intermediate (referred to in the Working Party's report as "doubtful"), where an application for admission will be considered in the light of the particular circumstances and where, if the application is granted, the doctor will not be entitled to the initial practice allowance;

restricted, where there are already enough doctors practising and the admission of new doctors will be exceptional.

The criteria for classifying areas into these categories have been agreed between the Medical Practices Committee, the General Medical Services Committee, and the Ministry. Although the new classification will not come into effect until April, the Ministry realise that doctors who are setting up in practice will be anxious to know whether they will be entitled to the initial practice allowance, and the Ministry hope to publish the new classification by the middle of October.

INTERNATIONAL BIOLOGICAL STANDARDISATION

BIOLOGICAL standardisation began when Ehrlich adopted one of his diphtheria antitoxic sera as a standard by which other sera could be compared, and it is fitting that the new international unit for tetanus toxoid should be approximately equivalent to the "*Schutzeinheit*" of the standard tetanus toxoid of the Paul Ehrlich Institute in Frankfurt-on-Main. The confusing number of different units for tetanus antitoxin gave the stimulus which led to international standardisation of antitoxic sera: before an international unit was established, the American unit equalled 2 British units, approximately 1/64th of a Frankfurt unit, and 40 French units. The first international unit, established for diphtheria antitoxin by the League of Nations, was defined in 1922, and this unit remained the only example of international coöperation in this subject until 1928, when units for tetanus antitoxin, antidysentery serum (Shiga), and ouabain were adopted. Since then progress has been more rapid, and standards have been adopted for antigens, vitamins, hormones, arsenicals, and antibiotics. Assay of some undefined substances can only refer to their biological activity, and certain complications may arise when one member of a group sharing common biological activity is compared with another member of the same group. In the vitamin-A group the international unit had to be redefined in the light of assessment by a non-biological method: and vitamin D_2 can have two values, depending on the experimental animal.

The World Health Organisation Expert Committee on Biological Standardisation which has just issued its fifth report,[1] has added several standards, including blood-grouping sera, *b*-carotene, vitamin D_3, adrenocorticotropic hormone, *d*-tubocurarine chloride, and streptomycin. There are also reference preparations, to which units have not yet been assigned, for diphtheria toxoid, cardiolipin, lecithin, and penicillin-K. Investigations are in hand to establish standard preparations of bacteria for making diagnostic sera and for prophylactic inoculation, and standards for mammalian and avian tuberculins and for enzymes, such as hyaluronidase and thrombin. New antibiotics need standardising, and the committee have advised that author's preparations should be collected by W.H.O., and the nature and size of provisional units assigned after consultation with the author. Material has been collected for standards for aureomycin and terramycin, and is now being collected for chloramphenicol and bacitracin. The committee has asked the National Institute for Medical Research to undertake a study of pyrogens, both as therapeutic agents and as unwanted contaminants of other preparations. The aim is to establish an international reference preparation of pyrogens. In collaboration with a subcommittee on the serology of venereal diseases, stable reagents, including freeze-dried syphilitic sera, for the calibration of serological tests, are being developed.

Ultimately all biological materials may be defined completely by chemical analysis when there will be no need for assay; but the time seems a long way off.

SIR JACK DRUMMOND, F.R.S.

Sir Jack Drummond, whose untimely death was reported from France on Aug. 5, was a biochemist of rare versatility. As professor at University College, London, he was keenly alive to the importance of the biological aspects of his subject; and he was always reluctant to separate his department from that of physiology. His own investigations, begun at the Royal Cancer Hospital, were mainly on the fat-soluble vitamins; but in the academic sphere his most important contribution was not through research but through training younger men, and two successive holders of the chair at Cambridge are among those who passed through his department. To the public he was best known as scientific adviser to the Ministry of Food in the late war. Here his bent for applied science found full play; and he played a large part in evolving the successful rationing system in this difficult time. Industry, too, owes him much. No false academic pride inhibited him from giving of his best to this field, in which, after the war, he concentrated his energies; and here once again he led in the training of others.

To those who knew him he was a good friend and colleague, always ready to help anyone; his unobtrusive aid enabled more than one student to attend the university. Vigorous and well informed, with a keen sense of humour, he enlivened any gathering. Himself friendly and sociable, he sought to avert discord between others. Some will recall an important scientific meeting when two violently opposed points of view were to be expressed. When the day came, the expected collision did not take place; he had helped to bring the protagonists together informally. In the war his characteristic determination to see every job through to the end often took him far from his desk. To this work, as to all else, he brought an integrity that none could dispute.

HARROW CHEST CLINIC, MIDDLESEX

> "Epidemics of tuberculosis are rarely reported, probably rarely discovered. The outbreak reported this week . . . leads one to believe that it is the detection of outbreaks which is rare, and not their occurrence."—*British Medical Journal*, 1951, ii, 840.

DURING the past eighteen months sporadic cases of tuberculosis in children attending nine day-schools in the Edgware and Harrow Chest Clinic areas have led to the examination of 3422 school-children between the ages of 6 and 18, and 118 teachers. Nothing in the nature of an epidemic was discovered but in view of the comment quoted above we report the results and our conclusions.

METHODS

In all cases the coöperation of the headmaster and the medical officer of health was sought. The latter arranged for all the parents to be asked to consent to the examination of their children. It was also arranged with the individual school authorities that the presentation by them of a child for medical examination implied that the requisite written permission had been obtained from the parents. In some cases this permission was refused, but 94% of the parents approached gave their consent.

Different methods of making the survey were tried:

(1) The first method was to ask the appropriate mass-radiography unit to make the survey. At the first school only a radiological examination was made, but at the second a tuberculin-jelly test was incorporated at our request. Although we were grateful to the staff of the mass-radiography unit for doing this work, the method was not ideal. In the first place it was found that, owing to the heavy commitments of the unit, such a survey could not be undertaken without an interval of several weeks. Secondly, although the results of the tuberculin tests were given in age-groups, the clinic had no knowledge of the result in any individual case, and it was felt that this information could be valuable if the child was subsequently referred to the clinic. Further, any child absent from school on the day of the unit's visit missed examination altogether.

(2) The second method tried was for the clinic staff to do the tuberculin testing and for the mass-radiography unit to radiograph the pupils immediately afterwards. Difficulty was experienced, however, in arranging a mutually convenient time for the unit and the clinic staff within the school's time-table.

(3) In the schools subsequently surveyed the clinic staff conducted the whole survey.

Tuberculin testing was done with 0·1 mg. of tuberculin injected intracutaneously by one of the clinic physicians. Although we consider the patch test to be equivalent (Anderson et al. 1951), this method was considered to be quicker; we could test 700 children in a morning. It was also found that the plaster tended to come off accidentally or was removed deliberately, its significance not being appreciated.

Each pupil, on attending for tuberculin testing, brought with him a piece of paper on which was written his name, age, address, school, and class, and the name of his private doctor. These pieces of paper were collected and the names entered in a book under classes. A similar piece of paper was presented when the tuberculin test was read by the physician, who wrote the result on this paper. All positive reactors were passed on to a clerk, who gave them a letter asking them to attend at the Chest Clinic on the following Saturday morning for X-ray screening. This scheme was very satisfactory and expeditious. The senior teacher was also informed that any child absent could be seen at the Chest Clinic if the mother would telephone for an appointment.

Some children who did not attend the school survey were later referred by general practitioners to the "X-ray only" sessions (Trenchard and Grenville-Mathers 1952) for tuberculin testing and X ray; so nearly all the school-children were eventually examined.

At one school this procedure unfortunately could not be followed. Three cases of presumed tuberculosis in this school were found only after the school had broken up for the summer vacation, and it was therefore arranged that the medical officer of health should circularise all the parents, pointing out the advantage of having their children X-rayed, and facilities were offered at the Chest Clinic on the next six Saturday mornings. This did not prove very satisfactory: 72 pupils were not examined at all, and many were found next term to have left the school.

At all surveys the school-teachers were urged to come forward for examination, but only 118 out of some 150 were examined.

ORIGINAL CASES AND RESULTS OF X-RAY SURVEYS

The following are the details of the cases leading to examination of the schools, and the number examined out of the total on the school roll.

School 1

At this school a boy, aged 12, was found to have a pleural effusion, and a month later another boy, aged 12, was found to have enlarged hilar glands. The domiciliary contacts were healthy. The mass-radiography unit examined 385 boys out of 437, and 7 teachers out of 22. No further cases were found.

School 2

A boy, aged 15, was found to have primary tuberculosis, and the mass-radiography unit did the tuberculin-jelly testing and radiography of 490 children out of 550. No teachers were examined. No further cases of tuberculosis were found.

School 3

A girl, aged 16, was found to have tuberculosis, with positive sputum, in August. All the 688 pupils and 28 teachers were examined in November without any further cases being discovered.

Schools 4 and 5

A girl, a domiciliary contact aged 14, was found to have tuberculosis, with positive sputum, in August, and in October a boy, aged 13, was found to have a pleural effusion. The two schools shared the same buildings, and some of the staff taught in both schools; so they were treated as one unit, and the pupils of both were examined in October. Of the 1030 pupils 998 were examined and 52 out of the 61 teachers. No cases of tuberculosis were found, but one pupil, aged 14, had a small round focus in the left second intercostal space and has been kept under observation at the clinic.

School 6

During July, 1951, the mass-radiography unit was operating in the Harrow area and offered to radiograph those girls of this school who were aged 15 or more. One girl, aged 15, was found to have tuberculosis with a positive sputum, and another girl, aged 15, enlarged hilar glands. This latter girl lived outside the area, and it was later found that she was a domiciliary contact. A third girl, aged 15, was found to have a pulmonary lesion, but on further investigation this was proved to be non-tuberculous.

Of 550 pupils 478 were screened, and 16 of the 32 teachers. These 16 included all the teachers who taught the above-mentioned girls. Again no further cases of tuberculosis were found.

School 7

At this school a girl, aged 16, was found to have bilateral tuberculosis, with positive sputum in July. In November a girl, aged 19, who had recently left the school, was found to have bilateral tuberculosis with positive sputum; a teacher, aged 30, was diagnosed as tuberculous with positive sputum; and a pupil, aged 15, was found to have a pleural effusion. 308 of the 310 pupils were examined and 15 of the 16 teachers. No further cases of tuberculosis were found.

Schools 8 and 9

A girl, aged 12, living outside the area, developed a pleural effusion. The domiciliary contacts were reported to be free from tuberculosis. She attended a school inside the area, which eighteen months before had been included in a survey by the mass-radiography unit during its visit to the district. Tuberculin-jelly tests were made on 35 children of her class at school, among whom 5 positive reactors were discovered,

RESULTS OF TUBERCULIN TESTS

Age-group (yr.)	School 2		School 3		Schools 4 and 5		School 7		School 8		All schools	
	No. tested	No. tuberculin-positive	No. tested	No. tuberculin-positive	No. tested	No. tuberculin-positive	No. tested	No. tuberculin-positive	No. tested	No. tuberculin-positive	No. tested	No. tuberculin-positive
11+	58	5 (*8·6%*)	66	12 (*18·1%*)	202	21 (*10·4%*)	35	2 (*5·7%*)	..	..	361	40 (*11·0%*)

Total ..	472	..	652	..	991	..	296	..	35	..	2446	..

At schools 2 and 8 tuberculin jelly was used: at the remainder 0·1 mg. of tuberculin intracutaneously.

but these were normal on radiography. The headmistress was most reluctant for further examination to be undertaken, and in view of the low proportion of positive reactors in the class concerned it was considered reasonable to accede to her request. The teachers were not radiographed but had been included in the earlier mass-radiography survey.

A girl, aged 6, was found to have a primary tuberculous lesion. The domiciliary contacts were normal on examination. Tuberculin-jelly tests were performed on 40 children aged 6 at the school she attended. The results were negative in the children, and 3 teachers who had been in contact with the group of children were radiographed and found to have normal lung fields. In view of these findings no further survey was undertaken at the school.

RESULTS OF TUBERCULIN TESTS

Of the 3422 pupils examined 2446 had a tuberculin test. The results for the different schools are given in the accompanying table, an asterisk being placed against the age-group from which the original cases came at that school. The differences in the percentage found positive do not seem to be of any significance for the relatively small numbers involved, and do not point to any spread of infection among the school-children. This is confirmed by the failure to discover further cases of tuberculosis.

COMMENTS

It is not surprising that a pupil with open pulmonary tuberculosis (as in schools 3, 4, 5, and 6) is not responsible for gross dissemination of tuberculosis in day-schools, since such a child usually makes his friends among those in his own class and does not mix with others to any great extent. Even in the dining-room the pupils do not, as a rule, mix.

The position seems to be very different if a school-teacher has pulmonary tuberculosis; for in school 7, where a teacher had the disease, 2 other cases of moderately advanced tuberculosis and 1 case of pleural effusion occurred. This danger from school-teachers is confirmed by the reports of school epidemics (Arnould 1933, Bevan et al. 1951, Hyge 1947, Pache et al. 1943, Roe and Dick 1949) in each of which a teacher was the source of infection.

CONCLUSIONS

As a result of these surveys we feel that, where a case of tuberculosis occurs in a day-school child, full examination of all the school population is not necessarily required. As reported here, it is probably only necessary to radiograph the staff and examine the other pupils in the same class by tuberculin testing, and later to radiograph the reactors.

The position is vastly different where a school-teacher is the source, and all the school population then needs to be examined. The better way is to prevent such occurrences by the regular radiological examination of school-teachers. Many local authorities stipulate that teachers *may* be required to undergo radiography, but this has not always been enforced even at the preliminary medical examination on entering the school service, and the teachers themselves are strongly averse to periodic radiography. Thus one headmaster in this series, when sent dates on which further members of his staff could be examined, refused to inform his staff. Since the parents had had the option of refusing to have their children examined, he felt that the staff should have the same option. As from the summer of 1953 the Ministry of Education have made it compulsory for all school-teachers to undergo a preliminary radiological examination, and teachers resuming duty after absence due to tuberculosis will be required to produce frequent medical certificates, but there is no compulsion for periodic radiography of presumably healthy teachers, and no supervision is required of those having questionably active disease.

The reluctance of teachers to be radiographed frequently is understandable, since a diagnosis of tuberculosis can be catastrophic for them. We have recent knowledge of a school-teacher having considerable difficulty in finding suitable work when he could not return to teaching. Yet, if tuberculosis in children and young adults is to be prevented, it is advisable that the radiography of adults working in close contact with children be made compulsory. Such a regulation could not be introduced, however, without at the same time guaranteeing to any teacher found to have tuberculosis full pay for an unlimited period during treatment until he could safely return to his post or find other remunerative employment.

We are indebted to Dr. T. Paxon for the assistance of his mass-radiography unit in some of these surveys and Dr. H. J. Trenchard for his criticisms and some of the figures. Our thanks are also due to Dr. W. E. Caryl Thomas, the area medical officer, and to Miss E. Last.

Poliomyelitis

Poliomyelitis notifications in the week ended Aug. 2 (the 31st week of the year) were (previous week in parentheses): paralytic, 139 (157); non-paralytic, 91 (96); total, 230 (253).

The following table compares this year (up to and including the 31st week) with the preceding five years.

Year	*Total cases up to and including 31st week*	*Cases in 31st week*
1947	1628	487
1948	873	43
1949	1203	187
1950	2593	367
1951	1399	117
1952	1660	230

Up to and including the week ended Aug. 2, the over-all notification-rate for England and Wales was 3·8 per 100,000 population.

Points of View

THE PROSPECT OF GENERAL PRACTICE

FROM A CORRESPONDENT

THE general practitioner is repeatedly said to be the really important man in medicine; but every influence, professional, official, social, and economic, goes to make his position less secure and his work less satisfying.

In the great medical schools the finger of scorn is often pointed at general practitioners, though some lip-service is paid to the institution of general practice. The reasons for this are not far to seek. In the prevailing atmosphere of intense specialism much of the interest in hospital wards centres in cases which are not only beyond the scope of treatment of general practice but also beyond its experience. It is inevitable that the "poor old G.P." attitude should develop; and it is of course exacerbated by the often appalling mistakes seen in hospitals as a result of low professional standards, and lack of opportunity for good work, of individual practitioners. At the same time an intense respect is inculcated for academic brilliance and high technical skill in scientific medicine. Add to this the great personal influence of a respected physician or surgeon upon a newly qualified man, compounded as it is of personal affection, admiration, and a good deal of envy, and it becomes clear that very powerful mental and emotional influences are at work to turn students from the consideration of general practice as a career.

In my own case five years of academic research (which nevertheless had a severely practical application) followed on the year and a half of hospital work, and provided intense intellectual satisfaction. But my leaning to general practice persisted in the background, and recently has recurred strongly as a dominant vocation. There is therefore an acute tension to be resolved, which can most simply be expressed by drawing up a balance-sheet.

ON BALANCE

First, general practice is the field of closest and most intimate professional relationships. The general practitioner, especially in the country, has great opportunities of knowing the sort of experiences which have influenced the life of an individual patient, and will influence it in the future. There is also the attraction of dealing with a whole family; for, after all, the family matters in society above all else. It is the natural social unit, it is the source of personality in a way which is only beginning to be appreciated, and it is the natural sphere in which men and women are, on the whole, required to work out their own salvation. Apart from the family there is no society, no order, no moral code, no peace, no love, no joy. For the common man, the family is the vehicle of the kingdom of heaven as certainly as it is the only stay of a stable and creative society. Knowledge of the family enables a doctor to assess more reliably the interplay of factors producing a given illness, and his relationship gives him an influence—out of all proportion to his ability and training—on the most vital human relationships. Moreover, he can enter general practice without using the faces of his fallen colleagues as stepping-stones to success. Many of my generation know this unpleasant necessity in the rush for specialism.

Turning to the objections to general practice, these are not based solely on the existence of the National Health Service, though this has undeniably intensified some dissatisfactions. The trouble lies in the whole trend of general practice since the early part of the century, and the whole situation as it stands at present.

For the younger generation, especially the brighter ones, general practice is only to be resorted to when all else fails. My own reasons against it can be put down in order of precedence, as follows:

1. I have been trained as a scientist and a specialist and taught to admire high technical skill and professional competence; a high standard of intellectual attainment has constantly been set before me throughout my training and I value it very greatly. Is there any chance of my having conditions of work in general practice which will allow me to exercise my technical skill or satisfy my intellectual thirst? Emphatically, no. I shall be too busy to examine or follow any case adequately, and I shall not be able to have the equipment for scientific diagnosis and treatment; nor, if I had it, should I have time to use it.

2. My wife and I want to be able to bring up our family under decent conditions; we want them to be moderately civilised and well-educated and to have a happy family life. Whatever kind of schooling the children may get, there must be order and leisure in their home. Will general practice allow us to do this? Once more, emphatically, no. If I have sufficient patients to make a good living,[*] I shall work roughly from 9 A.M. to 11 P.M. six days a week, and at any rate for my first five years shall be able to have no holidays because locums are so expensive. My wife will have to bear the whole domestic burden, with such daily help as she can tempt into a doctor's house, and my children will have to be kept out of the way so that the consulting- and waiting-rooms are not disturbed by their exuberance. Someone must be on duty in the house 24 hours a day 365 days in the year, since it is an indictable offence to leave the telephone unattended. My wife will either become a saint, or a slut, or leave me; my children will be sent to boarding-schools as soon as possible, so that the practice may go on undisturbed; as they grow up they will be left entirely to their own devices and we shall never go out with them together again. Of course, we are already resigned to our never going to entertainment or worship together again for the next 10 years, just because we have children.

3. If medicine is to be adequately practised it must be pursued without thought of gain and without the blackmail of hostile circumstances. Does general practice under the N.H.S. allow this? No. I shall be more a tradesman than ever my father was. The State patient has the whip hand; whatever insult, stupidity, thoughtlessness, or unnecessary demand he may submit me to, I must smile and comply. Not only can he leave me (with his whole family) without inconvenience or compunction, but he can involve me in endless anxiety, loss of time and legal expenses by reporting me to the local committee, without any inconvenience to himself.

4. If my health falters, if my principles conflict with the Ministry of Health, if my work leads me to make mistakes in my records, if an influential competitor gets a seat on the Regional Board not only are my hopes of advancement killed, but my very livelihood endangered.

---

[*] We should perhaps make it clear that this article was written before the Danckwerts award was announced.—ED. L.

Shall I enter general practice? Not if I can avoid it!

WHAT ARE THE HOPES?

So it is that the queue for specialisation grows and grows, and those that at last sink into general practice are bitter and frustrated near-specialists, hating themselves and their jobs. Their chances of getting out again, once they have got in, are nil. The family doctor is urgently needed and is anxious to come forward in the service of many families, and of his own. If he risks everything on his gamble he may fail the many families by betraying his scientific training and being too busy to listen or examine, or with failing his own family by exposing them to a neglect they ought not to be asked to bear. Is there then no hope? Must he be either professionally incompetent, poor (because he limits his list to what he can adequately deal with), or a stranger to his wife and children?

It has been suggested that the only hope for general practice is to create chairs of general practice at the universities, so that there may no longer be a divorce between learning and practice, between medical education and the occupation of most doctors. This is an idea with a sound basis, but so far divorced from practical possibility at present as to be quite out of court. A G.P. elevated to a professorial chair could be little more shrewd than Sancho Panza in his governorship—and as ridiculous to his academic colleagues and students. He would carry no academic weight, and so get no hearing.

A man's work must itself satisfy his creative potentiality—it must justify him as made in the image of God. This principle, expressed by every poet and artist at odds with society, was perhaps practised sometimes in the Middle Ages; it is anathema to our industrialised society, and only exemplified now by the few surviving craftsmen and farmers still able to devote themselves wholly to a whole job. In medicine it is an ideal less and less attainable—in general practice because the personal relationship is shorn of intellectual and technical satisfaction, and in the specialties because the academic and technical skill operates in a sphere approaching more and more closely to a vacuum.

There is one great opportunity of redressing the balance at this time, and that is research, carried on in general practice.

> "General practice," the old men say, "offers endless opportunity for research, both social and medical."
>
> "When I am in general practice," a few young men say, "I shall do real scientific work."
>
> "I have done two surgeries and twenty visits to-day," says the general practitioner. "If I work every night from 8 to 11 this week I should get my paper-work done; but I know Mrs. X always has her babies at 3 in the morning."

Unless some young men can find opportunity, intention, strength of purpose, and financial backing to restore to general practice a scientific and academic respectability—not by talking about it, but, by being good family doctors and good scientific workers both at once—the outlook for general practice must be black indeed. A salary would help, by freeing them from the tyranny of the bottle of medicine and the time-waster (and why the medical profession should consider that a salary is the most stultifying manner of remuneration is one of the greatest mysteries of the contemporary social scene; it can only mean that its faith in its own standards has fallen to zero); but that is now a political issue and probably will not be decided for years to come. Some few with an academic background and a vocation to family medicine must find sufficient funds to go into general practice, limit their list to 1500 or so, and tackle a research programme with seriousness and ability. It is only by results that general practice can now re-establish itself in the academic scene.

Special Articles

MALARIAL FEVER THERAPY

P. G. SHUTE
M.B.E., F.R.E.S.

ASSISTANT DIRECTOR, MALARIA REFERENCE LABORATORY, HORTON HOSPITAL, EPSOM

THE reports that malaria therapy has benefited several cases of nephrosis (Byrne 1952, Gairdner 1952) have led to numerous requests to the Malaria Reference Laboratory, Horton Hospital, Epsom, for malaria material and for suggestions about the care and management of induced malaria.* The applicant is informed whether mosquitoes will be brought to his hospital, or whether parasitised blood will be sent. As live mosquitoes are not allowed to be sent through the post, they are carried by an assistant, who induces them to bite the patient to cause malaria.

INFECTION BY MOSQUITOES

A hot-water bottle should be placed against the patient's thigh an hour or two before the mosquitoes are applied. No other preparation is necessary, and on no account should the patient's skin be cleaned with soap and water or other antiseptics. Irritation from the bites of the mosquitoes can be relieved by dabbing the area of the bites with cotton-wool soaked in methylated spirit or methyl alcohol. Some patients experience irritation immediately after being bitten, whereas in others it may be delayed for as long as twenty-four hours.

Parasite Used

Only one species, *Plasmodium vivax* (benign tertian) is recommended for malaria therapy. Malaria due to *P. falciparum* (malignant tertian) is too severe; that due to *P. ovale* is too mild, recovery usually occurring spontaneously after 4–6 pyrexial peaks; quartan malaria, due to *P. malariæ*, is erratic in its behaviour and usually has a very long incubation period.

The strain of *P. vivax* supplied by this laboratory is known as the Madagascar strain. It was originally isolated from a lascar seaman in May, 1925, and since that date it has been kept in man-mosquito-man. The advantage of using this strain is that, as it has been under continuous observation for twenty-seven years, its behaviour in man and mosquito is known and its response to various drugs has been tested. For example, it is susceptible to mepacrine, quinine, proguanil, and 'Daraprim' (pyrimethamine).

Incubation Period

With this strain of parasite the incubation period is 9–14 days. Even if the mosquitoes inject enormous numbers of sporozoites the incubation period cannot be less than 9 days, because it takes 7 or 8 days for the sporozoite to complete its cycle in the parenchyma cells of the liver; and, when this is completed, at least one generation of the erythrocytic cycle must develop before fever can begin.

INFECTION BY INOCULATION

When whole blood containing malaria parasites is used to infect a patient, venous blood is taken from the donor and is either defibrinated, citrated, or heparinised. Our present technique is to send heparinised blood, about 5 ml. for each case, in a small screw-top container.

Just before use, the syringe and the needle should be thoroughly bathed in cold sterile saline solution. Spirit would kill the parasites.

Our practice is to inject the blood intramuscularly just below the scapula. The blood can be given intravenously, but the incubation period of malaria induced by erythrocytic parasites, unlike that of mosquito-induced malaria, is influenced by the number of parasites injected. It has been our experience over many years that where the incubation period is only 2 or 3 days, as it often is when large numbers of parasites are injected intravenously, the *subsequent fever is more severe than* it usually is when the incubation period is 9–14 days. When about 5 ml. of blood is given intramuscularly, the *incubation period is 10–16 days, seldom longer.* Failures sometimes occur because (1) the parasites may have died in transit; (2) they may have been killed by antiseptics; or (3), if the patient has had malaria before he may be immune.

---

* Any doctor may send to this laboratory blood films for examination and mosquitoes for identification.

Subinoculation

Where there are several patients to be treated and one of them has been successfully infected with malaria from this unit, the rest can be infected by inoculation from the first patient. If the donor is in the same ward, a few millilitres of venous blood can be drawn off and injected without delay; but if the patients are in different wards, or if the blood has to go to another hospital, the blood should be treated with heparin to prevent clotting. As already stated, the syringe should be bathed in cold sterile saline solution immediately before the blood is drawn off.

Time for Taking Blood for Subinoculation

It is often *supposed that during certain periods of an* attack of malaria the peripheral blood is free from parasites, and that subinoculation can therefore only be successful at certain times. Though this is true for *P. falciparum*, which completes its asexual cycle in the internal organs, it is not so for *P. vivax*, whose complete cycle takes place in the peripheral circulation, and therefore the blood is infective at all hours from the beginning of the attack until antimalarial drugs are given. However, it is advisable to take blood for subinoculation a few hours after the termination of an attack of malaria because *at this time the young parasites are securely* attached to fresh erythrocytes, and the patient is usually feeling fairly comfortable after the cold and sweating stages. Blood should always be taken when young forms of the parasite are present if it is to be kept for a day or two, and it should be stored on ice.

PYREXIA IN PRIMARY *P. vivax* MALARIA

In about 86% of our primary cases of benign tertian malaria the fever has been quotidian and not of classical tertian type. There is abundant evidence to show that this quotidian fever is due to an absence of tolerance or premunition, because when relapses occur in the same patients the fever is almost without exception tertian and *after a few attacks of fever the tendency is towards* a spontaneous recovery clinically but not necessarily parasitologically.

The over-all clinical picture of benign tertian malaria of the Madagascar strain can be divided into five distinct phases:

(1) *Initial fever* usually lasts 3–5 days and is irregular, the temperature seldom rising above 102°F, and it may not return to normal throughout this period.

(2) *Developed stage.*—Fever is quotidian, temperatures of 104°F and 105°F are usual, rigors may or may not occur, and after 5 or 6 attacks the patient feels rather exhausted.

(3) *Terminating stage.*—After ten or more uninterrupted attacks of fever the tendency is towards spontaneous recovery, but this depends on the amount of resistance which the patient has built up as the result of his previous attacks. The first indication of spontaneous recovery may be the fever's sudden change from quotidian to classical tertian; but *this does not always* happen, and patients who are having quotidian fever may recover spontaneously, although parasites may be plentiful in the blood.

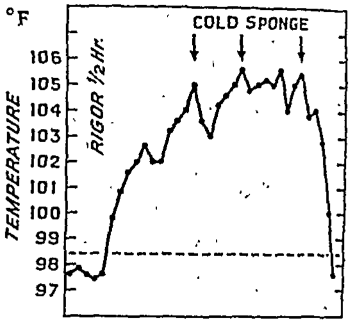

Fig. 1—An attack of benign tertian malaria due to a single group of parasites and lasting 8–10 hours.

(4) *Chronic stage.*—After a spontaneous recovery, either from the primary attack or from a relapse, parasites may be quite numerous in the blood and may continue to be so for several weeks unless antimalarial drugs are given. Although there is no pyrexia, the parasites are continuing their development, and therefore antimalarial drugs should be given to prevent anæmia.

(5) *Immunity.*—In primary benign tertian malaria patients who have had ten to twelve attacks of fever and perhaps one relapse some months later, can seldom be successfully reinfected *with the same strain of the same species of parasite.* If, however, the primary attack is cut short, subsequent relapses at about monthly intervals over a period of several months are frequent. Such patients have not been allowed to build up much tolerance or immunity and are therefore susceptible to reinfection. In other words, *relapses are evidence of* non-immunity, and the cessation of relapses, unless due to antimalarial drugs, is evidence of immunity.

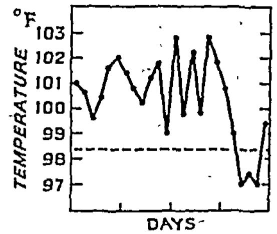

Fig. 2—Intermittent fever for 2 or 3 days in early stages of benign tertian malaria due to two or more groups of parasites.

(6) *Rigors* are common in benign tertian malaria, especially in the developed stage (stage 2). If, *however, the patient develops his* attack either daily or every other day with clock-like precision, much of the discomfort and severity of the rigor can be reduced if hot-water bottles and extra blankets are applied an hour or so before it is expected.

CARE AND MANAGEMENT OF INDUCED MALARIA

An attack of benign tertian malaria due to a single group of parasites usually lasts about 8 hours (fig. 1). In the early stages, where the fever is intermittent for 2 or 3 days, this is because two or more groups of parasites are present and each group is capable of causing fever (fig. 2). If the fever is quotidian, it is usually advisable to change it to tertian or to abort the attack temporarily. A single intramuscular injection of 0·2 g. of 'Thio-Bismol' (Parke Davis) will in most cases change quotidian fever to tertian. This drug seems to have a selective action on the half-grown asexual parasites, with the result that there is no pyrexia on the day after it is given, and subsequently the fever is tertian (fig. 3). This dose is for an adult and should be adjusted

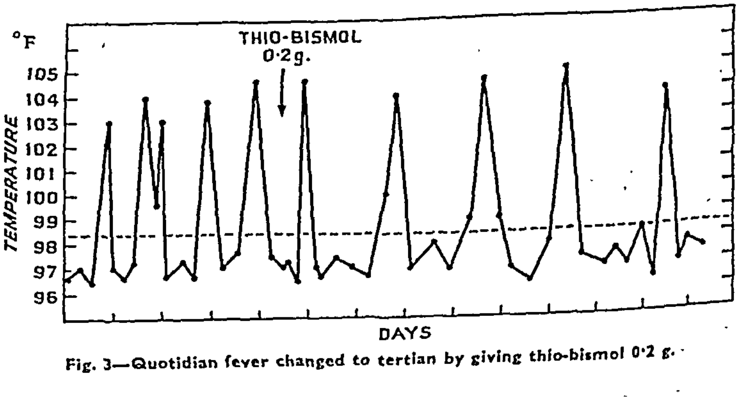

Fig. 3—Quotidian fever changed to tertian by giving thio-bismol 0·2 g.

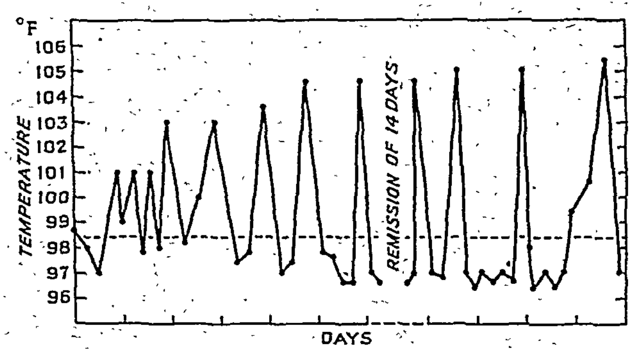

Fig. 4—Remission of fever for 14 days after quinine gr. 5, followed by recrudescence of fever as tertian instead of quotidian.

for children. If thio-bismol is not available, or if it is decided to give the malaria therapy in two stages, a single dose of quinine gr. 5 or of mepacrine 0·3 g. given orally will abort an attack for 10–14 days, when the fever will begin again, and often the fever of a recrudescence will be tertian (fig. 4). These doses are for adults.

Termination of Attack

Proguanil 0·2 g. daily for 10 days, mepacrine 0·3 g. daily for 7 days, and quinine gr. 5 daily for 15 days are adequate against the Madagascar strain of benign tertian malaria. These doses are based on observations for adults and should be adjusted for children.

Recording of Temperature

Although an attack of fever usually lasts about 8 hours, the peak of pyrexia may last only 1 or 2 hours; so 4-hourly temperature recordings are insufficient. It is our practice to take the temperature every 20 minutes or at least every half an hour once the attack has started, and this is continued until the temperature falls two or three degrees and it is seen that the attack is over. These frequent temperatures are recorded in a notebook, and the following day six readings are selected and recorded on the 4-hourly chart. If temperatures are taken only 4-hourly, the highest temperatures may be missed.

There is considerable dehydration as the result of an attack of malaria. Accordingly, after the sweating stage, glucose drinks, sweet lemonade, &c., should be given.

The Spleen

In primary malaria the spleen quickly becomes much enlarged, but it is very soft and often not palpable, probably because the patient is resting in bed; it is very different from the hard enlarged spleen of chronic parasite carriers in hyperendemic areas where the patients are up and about. Patients undergoing malaria therapy should be safeguarded from sharp active movements when changing position in the bed, so as to avoid spontaneous rupture of the spleen.

Relapses

With the Madagascar strain of benign tertian malaria relapses occur in about half the patients infected by mosquito bites. Usually there is only one relapse within a year from the primary attack; after this the patient is apparently immune to this species and strain of parasite. This, however, is conditional on the amount of fever in the primary attack. Patients who are allowed to have 12 or more peaks of fever in the primary attack seldom relapse more than once; but, if only 2 or 3 attacks are allowed, usually there are several relapses at monthly intervals or twice a month unless suppressive treatment is given. A relapse seldom occurs more than a year after the original infection. It is therefore suggested that patients who are allowed to have only a few attacks of fever in the primary attack and who relapse within 2 months of a course of antimalarial treatment should be given suppressive treatment for at least 6 months. Proguanil 0·2 g. twice a week will in most cases be sufficient. Relapses following infection by direct blood inoculations are unknown.

BLOOD FILMS

It is seldom if ever necessary to examine a thick blood film in induced malaria. The parasites are usually numerous, and except during the first 2 or 3 days of a primary attack one or more can be found in each of 25 micro-fields. A thin film is all that is wanted.

Slides.—Wherever possible new thin half-white slides with smooth edges should be used. Usually it is sufficient to pass new slides through methyl alcohol and to wipe them with a clean grease-free cloth. If, however, the slides are greasy they should first be cleaned with a detergent, such as diluted 'Teepol,' washed thoroughly, dried, and passed through methyl or absolute alcohol (methylated spirit should not be used).

Preparation of blood film.—The pad of the middle finger is cleaned thoroughly and when quite dry is sharply but gently pricked with a straight triangular needle. It is advisable to wipe off the first drop of blood and then, by a little pressure, to cause a bead of blood to form. The slide should be held by the edges to prevent grease from the fingers from getting on the surface of the slide. A bead of blood, no larger than the head of a pin, is brought into contact with the slide about half an inch from one end. The slide is then laid flat on a bench or table, and the edge of a second slide, held with thumb and index finger at an angle of 45°, is brought into contact with the bead of blood; after a slight pause, the slide is pushed along quite slowly but smoothly so that an unbroken film of blood covers about two-thirds of the slide. If the bead of blood is too large, the film will be too thick and if too much pressure in spreading the film is used, all the blood will be carried with the spreader. A little practice is required in preparing good thin films.

Staining malaria parasites.—Giemsa stain and Leishman stain are both satisfactory, but the sharpest picture is produced with Leishman stain. If Giemsa is used it should be bought in solution. 1 ml. of stain to 15 ml. of *neutral* distilled water is used for staining; but, because this is a watery stain, blood films must first be fixed for about half a minute *in methyl or absolute alcohol* (methylated spirit is unsatisfactory). Films should be stained for 15–20 minutes.

If Leishman stain is used, it is best to buy the crystals and make up the stain in the laboratory. 0·15 g. of the stain is added to 100 ml. of good-quality methyl alcohol. The bottle is shaken two or three times at short intervals on the day of preparing the stain, and it is then ready for use on the following day. Preliminary fixation of the blood film is unnecessary; but, if there is any delay and the film is lying uppermost on the laboratory bench, it is best to fix the film to prevent flies from devouring and contaminating the film. The film is stained by dropping on 4 or 5 drops of stain, and after 15 seconds (not longer) 10–12 drops of neutral or very slightly alkaline distilled water (pH 7·2) are added. The diluted stain is mixed thoroughly by rocking and allowed to stand for 15 minutes. The stain is washed off with a flood of distilled water and placed in a slanting position, with the blood film underneath, to dry. Artificial heat should never be used to dry a film stained by any of the Romanowsky modifications; but, if necessary, a film can be dried quickly by blotting with high-grade filter paper.

Parasite-count.—During the first day or two of a primary attack prolonged search is necessary to find even a single parasite, and sometimes none are found. From the third day onward there are usually at least two or more parasites in 25 micro-fields; in a well-prepared blood film, when the red cells are not overlapping but are nearly touching each other, there are about 400 red cells per micro-field when a $^{1}/_{12}$ in. oil-immersion lens and a no. 6 eyepiece are used. In the fully developed stage of a primary attack of benign tertian malaria there are usually about one or two parasites per field. In my opinion, in the practice of malaria therapy an attack should be aborted when this number is exceeded. It should be remembered, however, that for about 2 hours following a rigor, or in the absence of a rigor at the height of an attack, small ring forms of the parasite may exceed this number, but these will be seen to be much fewer if another film is taken an hour or so later, presumably owing to phagocytosis.

PREVENTION OF INFECTION OF LOCAL ANOPHELES

Thirty-two species of mosquitoes are known to be indigenous in Britian, but there are only four species of anopheles, and of these only one, *Anopheles maculipennis*, enters houses. The parasite of benign tertian malaria can develop in the tissues of anopheles when the temperature is 60°F or more. At about 75°F the cycle in the mosquito takes 10 days, but at 60°F it takes at least 30 days. In low-lying coastal regions where there is much brackish water *A. maculipennis* may become very numerous, and 50 or more are often seen in one bedroom. In inland districts the numbers are comparatively few. Patients undergoing malaria therapy between May and September should therefore be protected from mosquitoes, especially at night, either by sleeping under a mosquito net or in a side-room with the outer windows covered with mosquito netting. In hospitals in large towns the risk of spread is negligible or absent altogether.

MEDICAL APPOINTMENTS TO THE QUEEN

THE following appointments to Her Majesty's household have been announced:

Physicians.—Sir Horace Evans, K.C.V.O., F.R.C.P.; Sir John Weir, G.C.V.O., M.B., F.F.HOM.; R. Bodley Scott, F.R.C.P.

Physician-Pædiatrician.—Wilfrid Sheldon, F.R.C.P.

Extra Physicians.—Lord Horder, G.C.V.O., F.R.C.P.; Sir Henry Tidy, K.B.E., F.R.C.P.; Sir Daniel Davies, K.C.V.O., F.R.C.P.

Sergeant-Surgeon.—Sir Arthur Porritt, K.C.M.G., O.B.E., F.R.C.S.

Surgeons.—Sir James Paterson Ross, K.C.V.O., F.R.C.S.; Ralph Marnham, F.R.C.S.

Surgeon-Gynæcologist.—Sir William Gilliatt, K.C.V.O., F.R.C.P., F.R.C.S., F.R.C.O.G.

Extra Surgeons.—Sir Thomas Dunhill, G.C.V.O., C.M.G., F.R.C.S.; Sir James Walton, K.C.V.O., F.R.C.S.; Sir Lancelot Barrington-Ward, K.C.V.O., F.R.C.S.

Extra Manipulative Surgeon.—Sir Morton Smart, G.C.V.O., D.S.O., M.D.

Extra Surgeon-Apothecary.—Sir Frederick Hewett, K.C.B., K.C.V.O., K.B.E., M.D.

Surgeon-Oculist.—Sir Stewart Duke-Elder, K.C.V.O., F.R.C.S.

Extra Orthopædic Surgeon.—Sir Reginald Watson-Jones, F.R.C.S.

Aurist.—J. D. McLaggan, C.V.O., F.R.C.S.

Surgeon-Dentist.—A. C. R. McLeod, F.D.S., R.C.S.

Extra Physician to the Household.—Sir Arnold Stott, K.B.E., F.R.C.P.

Surgeon-Oculist to the Household.—A. J. B. Goldsmith, F.R.C.S.

Extra Surgeon-Oculist to the Household.—F. A. Juler, C.V.O., F.R.C.S.

Apothecary to the Household.—J. N. Loring, M.R.C.S.

Surgeon-Apothecary to the Household at Windsor.—R. W. L. May, M.B.

Extra Surgeon-Apothecary to the Household at Windsor.—E. C. Malden, C.V.O., M.B.

Surgeon-Apothecary to the Household at Sandringham.—J. L. B. Ansell, M.R.C.S.

Coroner of the Household at Windsor.—Lieut.-Colonel Leslie McCarthy, D.S.O., M.D.

SCOTLAND

Physicians.—A. Greig Anderson, C.V.O., F.R.C.P.; Sir John McNee, D.S.O., F.R.C.P.; Prof. L. S. P. Davidson, F.R.C.P.

Surgeons.—Sir James Learmonth, K.C.V.O., C.B.E., CH.M.; G. G. Bruce, F.R.C.S.

Surgeon-Oculist.—John Marshall, M.C., F.R.F.P.S.G.

Surgeon-Dentist.—R. C. S. Dow, L.R.C.P., H.D.D., F.D.S.

Surgeon-Apothecary to the Household at Balmoral.—G. P. Middleton, C.V.O., M.B.

Surgeon-Apothecary to the Household at the Palace of Holyroodhouse.—George Brewster, M.D.

In England Now

A Running Commentary by Peripatetic Correspondents

A PRECLINICAL colleague of ours has a profound distrust of electrons, even when suitably emboxed and under the strict surveillance of an expert. It appears that this distrust is mutual, for he has always been able to exert an inimical influence on the performance of any electrical apparatus merely by his presence in the vicinity. At his approach his friends cover up their electric clocks and muffle their refrigerators. In his lab. they have learned by experience to keep the thermostats in the basement and the embedding ovens in inaccessible corners.

Judge then of our colleague's dismay on finding that in his absence abroad his room had become the seat of feverish electrical activity. The whole of one bench was submerged beneath a smothering blanket of condensers, amplifiers, and rectifiers, while there were also several sinister black japanned cases mounted on rubber and undoubtedly containing numerous valves of the small malignant kind which never fit into any socket. Beneath the bench lurked two enormous batteries, and in the window, on his favourite seat, there stood the final ignominy, a trickle-charger. The floor was knee-deep in wire.

Our friend at once recognised the spoor of the electrophysiologist next door, who had not expected him back so soon. His wrath rose, and he said a naughty word. Revenge, however, was easy. He walked slowly round the room, pausing before each individual component of the prevailing chaos and fixing it solemnly with his eye. The immediate results were not spectacular, but the long-range effects are mounting daily. The apparatus has to all appearances been safely removed, but our colleague understands that square-wave pulses have been replaced by monophasic spikes, that the trickle-charger has caused acid to splutter all over various electrophysiological objets d'art, and that several dollar-consuming valves have blown. He is confident there will be no further encroachments the next time he goes abroad.

* * *

It is easy to introduce a new word into medical currency, but to discard it is more difficult. Hurst in 1915, with his enormous gusto, supplanted the word *cardiospasm* by *achalasia* and in 1921 could write, complacently and correctly, that "since I introduced it, it has been adopted by most writers on the subject." And now, in 1952, Douthwaite congratulates Avery Jones on excluding the inept word from his new book. Not only have the old gods fallen but their gospel is in fragments. Little enough remains of the codex, but how magnificent it looked in the 1920s.

Who would now do battle for these Hurstian concepts: the absent acid-barrier in pernicious anæmia; the inability of the cardiac sphincter to relax as a sequel to the degeneration of Auerbach's plexus; the ascending infection in acute hepatitis; the rôle of infection in gastric and duodenal ulcer; and the ætiological importance of chronic gastritis and chronic appendicitis?

And who practises these outworn therapies: rigid ulcer diets, intestinal lavage, dental clearance in pernicious anæmia, hexamine in cholecystitis, gastric lavage by iced water in hæmatemesis, the mercury bougie in cardiospasm, antidysenteric serum in ulcerative colitis, adrenaline by the minim-a-minute method, and the elimination of septic foci—teeth, tonsils, and appendices?

And what remains? A conviction that hysterical conditions can be quickly relieved by suggestion; an irreversible notion that the physician should take a look for himself, radiographically, sigmoidoscopically, and gastroscopically; and some fundamental work in gastro-intestinal radiology.

These are not inconsiderable legacies. But any physician who knew Hurst would say that the half has not been told. His enthusiasm and confidence were a consuming flame that cured his patients, convinced his colleagues, and warmed the coldest conferences. He was a magician whose faith made miracles possible and whose miracles created faith. Is such therapeutic magic part of the forgotten art of medicine? I am not sure, but it was certainly the glory that was Hurst.

* * *

As a junior peripatetic, I sometimes wonder if senior colleagues undergo what I undergo. In the past ten months I have had three mild attacks of Acute Appendicitis. With November came my First Disc, now happily back in hibernation. After Christmas I developed Bronchiectasis for 8 days, but surgical intervention was fortunately unnecessary. A week later I contracted Specific Disease, the result of too close an inspection of a beastly old aorta in the post-mortem room. This lasted for a fortnight, and was succeeded by a spasm of Carcinoma of the Gall-bladder—the anterior end, I could feel it quite distinctly. After a symptom-free month, I went down with my most trying illness to date—Primary Tuberculosis of the Epiglottis. For 5 weeks I suffered with sore throat, intermittent aphonia, and general malaise. Finally, rest, sedation, and spirits were instituted, and I went rapidly uphill, for by the time I could see my vocal cords in the mirror, all traces of the disease had disappeared.

With the exception of this last episode, my diseases have needed no treatment, but I would emphasise that this did not reflect an ignorance of available measures on my part. In fact the opposite was true, and I would strongly recommend all fellow juniors with a personal pathology to make good use of an invaluable aid to the learning of medicine.

At the moment I have an Œsophageal Hiatus Hernia. With reference to your excellent leader on the subject last week, I have to point out that I am not a middle-aged overweight woman of nervous disposition. The diagnosis was confirmed by the finding of borborygmi over the left atrium.

* * *

Not many people know how they are going to die, but I do. I shall be found dead in a taxi-cab. I shall die of the mounting threepences.

It is really a subtle form of homicide, this tormenting of frugal passengers with the detailed exactness of the sums dribbling from their pockets. Must we know it? Need there be an inside clock to draw our eyes with its horrid truths? Is it not enough to know the worst on alighting?

My health deteriorates only moderately at the initial one and threepence, for I am reconciled to that in advance. Nor do I suffer greatly from the grand total at the end, for I have a fair idea of what it will be. In fact I am sometimes restored to buoyant health by an over-estimate. No, it is the gradual and visible attrition which destroys my *élan vital*.

Try as I will I cannot withdraw my eyes from this menacing and implacable dial. If I sit with my back to it, it draws them irresistibly over my shoulder, and every time another threepence registers an iron hand clutches my heart.

How is it to be expected that the faithful son of a Scottish university should look on such a sight unmoved? Though long years of residence here have given me, I like to think, a little of the English phlegm. If I have company in a taxi I hope my cheek does not blanch nor my eye turn glassy, but I fear they do.

Naturally I avoid taxis as much as I can. My knowledge of bus routes and connections is unequalled, and my reputation with bus-conductors as a short-distance sprinter stands high. Nevertheless, emergencies will arise when only a taxi will answer. For instance, a sudden shower giving rise to acute hat-anxiety in the female. And then, the horrid ordeal of listening with affected pleasure to social chatter, and feigning nonchalance while this infernal machine ticks my substance away!

Yes, I shall die at my front door. The driver will send for a doctor. The police will arrive too. The taxi-man will state that he had been held up by several traffic jams, during which I had shown great agitation, and that I was alive immediately before arrival as I had pointed out the house to him in a voice trembling with emotion. Yet when he opened the taxi door I was dead.

The constable will murmur something about inquests and post mortems. But the doctor will smile knowingly. "Heart for a certainty," he will say. "See these stains on his waistcoat? Obviously porridge. The metre shows a fare of seven and sixpence. And just as the cab stopped *it ticked up another threepence*, and that finished him off. Couldn't take it. Quite simple——"

Letters to the Editor

ISONIAZID FROM THE RECEIVING END

SIR,—Isoniazid, since it is cheap to manufacture and easy to administer, is already being used extensively in the treatment of tuberculosis. So far little evidence of toxicity has been recorded. In the words of one doctor, "there was no toxicity worth talking about." Perhaps his patients were not very talkative. At any rate, I would like to register a protest from the receiving end.

After a total of 25 g. streptomycin, in association with P.A.S. 12 g. daily, I developed a mildly staggering gait. The streptomycin was, therefore, replaced by isoniazid 100 mg. t.d.s. (a daily dose of 6 mg. per kg. body-weight) and the P.A.S. continued. At this stage I had been afebrile with a steady pulse-rate of 70–80 for several weeks and, apart from mild gastro-intestinal disturbance due to P.A.S., was feeling well.

I was lying happily in bed under an oak-tree, reading the first volume of Sigerist's *History of Medicine*, when, to my surprise, about an hour after the first dose of isoniazid every nerve in my body seemed to have been stimulated. All the sites where streptomycin had been injected became painful, there was a sensation of tingling all over, together with generalised muscular twitching, and cardiac action became rapid and bounding. This state was associated with a complete inability to concentrate on the mysteries of medicine in ancient Mesopotamia. A period of drowsiness followed, but was soon dispelled by the next dose.

After a few days' treatment I had completely lost my appetite and was unable to sleep or even lie still. Sigerist was replaced by Sapper, but even the adventures of Bulldog Drummond were unable to hold my restless mind. I was uncomfortably aware of my physical surroundings; the trees seemed greener and the sky bluer; minor irritations had a greatly exaggerated importance. I was subject to attacks of palpitation and at rest alarming extrasystoles. After 6 days I had lost $3^{1}/_{2}$ lb. in weight and treatment was stopped.

I would like to remind those responsible for the treatment of tuberculosis that Keats wrote his best poems while dying of this disease. In my opinion he would never have done so under the influence of modern chemotherapy.

A PATIENT.

BLOOD-PRESSURE ESTIMATIONS IN CHILDREN

SIR,—Your leading article of Aug. 2 on the Treatment of Bacterial Meningitis says: "Meanwhile, doctors treating meningococcal infections will do well at first to chart the blood-pressure every fifteen minutes . . . they will certainly obtain useful evidence of the pressures to be expected in septicæmic children without adrenal damage."

I would be interested to know how the blood-pressure is to be taken, not every fifteen minutes, but at all, in a baby of, say, 10 months. In such a child (as in the case described by myself and my colleagues[1]) the manometer-cuffs currently available may cover the upper limb from the shoulder to the wrist, and the lower limb from the upper thigh to the middle of the leg. Which vessel is then to be selected? Moreover, the child, unless moribund, must be expected to resist, which will not enhance the accuracy of the results.

Again, for how long are these fifteen-minute readings to be kept up? The process would seem to offer abundant employment to at least one doctor for some twelve to twenty-four hours. In fact, Sir, I would venture to suggest that you have not considered the practical problems involved with your usual care.

South Middlesex Hospital,
Isleworth.

G. E. BREEN.

*** We should have made it clear that we were referring to research on the value of cortisone in the Waterhouse-Friderichsen syndrome. As Dr. Banks[2] pointed out in his letter commenting on Dr. Breen's paper, the diagnosis of the syndrome is extremely difficult. When a drug as powerful and as expensive as cortisone is in question, all possible care is indicated in its trial. The blood-pressure is, we understand, recorded as a matter of routine in many children younger than 10 months—e.g., in children with burns and scalds, and in pink disease. In those centres where retrolental fibroplasia is treated with A.C.T.H., regular readings are made on premature infants weighing less than 4 lb.[3] Dr. Breen is unfortunate in having only the adult-type manometer cuff: cuffs for children are now obtainable, and the 'Crista' range, sold by Messrs. Hawksley & Son, 17, New Cavendish Street, London, W.1, has three sizes. In older infants the mercury sphygmomanometer is sufficiently reliable if serial measurements are made. In smaller infants and newborn children, a Pachon oscillometer and 2·5 cm. cuff have been found more accurate by some workers.[4] The correct size and application of the cuff are important in measuring the blood-pressure at any age.[5]—ED.L.

HOSPITAL HYGIENE

SIR,—The letter by "M.O.H." in your issue of Aug. 9 leads me to raise another aspect of hospital hygiene. I speak from experience as a patient in four hospitals in recent years. The Ministries of Health and of Food, the public-health authorities, and others, have long been trying to inculcate in the public the doctrine that the hands should be washed after using the W.C. Are the hospitals doing anything to spread this doctrine by example? In which, if any, are patients provided with means of washing after a bedpan? The defence will probably be that the practice would throw still more work on an already scanty nursing staff. But is it not at least a desideratum?

PUBLIC HEALTH.

RECURRENT ATTACKS OF MENINGITIS

SIR,—A young woman, aged $19^{1}/_{2}$, was admitted to this hospital on March 6, 1952, with headache and vomiting. Her previous history was as follows:

At the age of 11 she had been diagnosed as having meningitis, and there was no reason to doubt this for both she and her mother gave a description which fitted in very definitely with an attack of meningitis—meningococcal meningitis I would have thought, for they both described a typical rash.

She made an uninterrupted recovery and kept perfectly well until the age of 16 when she was admitted to this hospital on Jan. 17, 1950, with suspected meningitis. She had had a cold for a fortnight before admission, and then suddenly developed a severe headache.

There was marked rigidity of the neck and spine, and she was very toxic and lethargic. A lumbar puncture showed a very turbid cerebrospinal fluid under increased pressure. The pathologist reported: cells 17,400 per c.mm. (polymorphonuclears); stained film showed gram-positive diplococci; culture gave a scanty growth of pneumococci.

A further lumbar puncture on Jan. 24 showed: cells 130 per c.mm. (mononuclears); protein 45 mg., chlorides 734 mg., glucose 56 mg., per 100 ml.; no organisms seen on gram film; cultures sterile.

She was given intrathecal penicillin (50,000 units), intramuscular penicillin (500,000 units b.d.), and $1^{1}/_{2}$ g. of sulphamezathine 4-hourly. She had three intrathecal injections, and the other treatment was maintained for 11 days. She made an uninterrupted recovery and was discharged on Feb. 4.

The findings in her latest illness were:

On admission there was definite neck rigidity with some extension of the head. The reflexes, superficial and deep, were slightly exaggerated. Kernig's sign was positive on both sides. Temperature 102°F, pulse 122, respirations 22. Lumbar puncture showed turbid fluid under slight pressure. The pathologist reported: cells over 10,000 per c.mm., glucose 69 mg., protein 800 mg., per 100 ml.; no organisms seen on film or culture, but the C.S.F. gave a positive precipitin reaction with type II meningococcal antiserum.

She was treated with intrathecal penicillin (20,000 units), intramuscular penicillin (500,000 units at once, then 200,000 units 4-hourly), and 2 g. of sulphamezathine 4-hourly. Her temperature became normal within 24 hours, and only one *intrathecal injection of penicillin* was given. The patient was treated with 'Duracillin' (500,000 units b.d.), and progressed steadily to complete recovery.

She has now had three attacks of meningitis: meningococcal at 11; pneumococcal at 16; and meningococcal again at $19^{1}/_{2}$.

She is now being seen at monthly intervals, and so far she has been in perfect health with no sequelæ whatever.

Infectious Diseases Hospital,
Portsmouth.

IAN M. MCLACHLAN.

FRACTURES OF THE NECK OF THE FEMUR

SIR,—I was very interested to read Mr. Stamm's article of July 12; but, as on many previous occasions, there is one point I should like to comment upon.

For many years now I have given up nailing these fractures in *internal* rotation, and instead have fixed them in a few degrees of *external* rotation. The improvement in the results is almost startling.

I have published elsewhere the reasons for this. Here I shall mention only one. In many of these cases the back of the neck of the femur is so fragmented that if the fracture be rotated internally, and nailed in this position, there is no real bony contact posteriorally. This obviously diminishes the chances of bony union.

London, W.1.

F. P. FITZGERALD.

HASHISH

SIR,—Dr. D. McI. Johnson, in his letter of April 19 (p. 820), gives an interesting and plausible explanation of the symptoms observed at Pont St. Esprit. His quotation of Théophile Gautier from *Le Club des Hachichiens* and of the recent American studies on this subject have a counterpart in the experience of Carl Ludwig Schleich, the surgeon who in 1891–92 introduced infiltration anæsthesia into surgery. In his memoirs[1] he relates his short but nearly fatal connection with hashish addicts.

Invited by a fellow-student and driven by sheer curiosity, Schleich, who then had just passed his first M.B., went to this "Klub der Resignierten." He found about eight young men there, lying about in a half-naked condition, humming, muttering, and singing to themselves; one of them playing a flute and two others reciting parodies of Goethe's Erlkönig and of other poetry. They all pretended to be followers of Buddha and the then fashionable Schopenhauer, the philosopher of pessimism; they styled themselves *candidati mortis*. Schleich recalls that there was a lot of cigarette-smoking and drinking of liquor, and also of tea; he does not relate whether there was any hashish smoking or drinking, but after he had been solemnly addressed by one individual wearing a turban he was asked to uncover his arm in order to be "initiated" into the "club." Rapidly he was given an injection, after which he immediately lost consciousness. He recovered from this (cardiac?) collapse after a professor of medicine who had been summoned had administered three injections of camphor.

This happened around 1880, in the small university town of Greifswald in Northern Germany. Schleich further relates that five of the members of this "club" of hashish addicts became inmates of mental hospitals or committed suicide. Not one of the others was ever cured of the addiction to hashish in the form of injections.

Port Stanley,
Falkland Islands.

ŒSOPHAGEAL HIATUS HERNIA

SIR,—In reading your leading article of Aug. 2 I was interested in the close parallel between the probable mechanism whereby reflux from the stomach is prevented (Allison[1]) and that which prevents dribbling of urine in the female (Jeffcoate[2]).

As I understand it, reflux from the stomach may occur when the œsophageal hiatus in the diaphragm is relaxed, allowing the angle between the œsophagus and the upper surface of the cardiac end of the stomach to be straightened out. Jeffcoate has shown that stress incontinence of urine in the female occurs when the angle between the base of the bladder and the urethra is straightened out. The parallel to Allison's "parahiatal hernia" is cystocele. Each of these may occur without incompetence of the retaining mechanism. Each may be associated with incompetence when the retaining angle is lost.

University of Leeds. A. AMBERY SMITH.

REASON AND UNREASON IN PSYCHOLOGICAL MEDICINE

SIR,—It seems likely that Dr. Dillon (Aug. 2) missed the main point that I tried (perhaps unsuccessfully) to make in my first Croonian lecture. My argument was that, if in the human sciences one's approach to causality is limited to the establishment of efficient or final causes, one is apt to be bogged down in a false metaphysic. I cannot however go the whole way with Dr. Dillon and admit that natural science can altogether dispense with the notion of "dependable sequences" and remain scientific.

London, W.1. E. B. STRAUSS.

FEEDING DISORDERS IN INFANTS

SIR,—I hesitate to comment upon Miss Morrison's letter in your issue of Aug. 9, because Professor Vining manifestly needs no support from me; but the assertion that the cause of digestive disorder in infants is "practically always a wrongly balanced mixture" and "seldom due merely to underfeeding or overfeeding" cannot be allowed to pass unchallenged.

It is somewhat disturbing to read the advice given on occasion in the infant-management columns of the lay press. Infants with such symptoms as "fretfulness," "colic," "never seems satisfied," constipation, vomiting, and failure to thrive, are said to be suffering from dyspepsia, wind, and even overfeeding.

I remember one case in particular of an infant with these symptoms which had been given a weaker feed by its mother with no success. The comment and advice given was: "How right you were Mother, to weaken the feed, even so it should be weaker still." A specially balanced formula was sent under separate cover.

Now there is absolutely no mystery about most of these infants; they are simply underfed, some of them grossly underfed. Anyone offering more feed can prove this.

Underfeeding is one of the commonest faults of infant management, as Professor Vining, Professor Illingworth, and Dr. Charlotte Naish have repeatedly averred. One reason for its frequency may be that mothers tend to read not THE LANCET but Nurse Blank's column in their weekly journal. Such publications have a considerable responsibility to their readers, and because of this I suggest that their watchword should be simplicity rather than complexity.

Cow's milk is so similar to breast-milk that some simple modification only is necessary. The suggestion that "ingredients" should be "balanced" merely baffles a harassed mother, causing her to ignore the often obvious symptoms of hunger in her baby.

There seems to be a belief that the mere male, by virtue of his sex, cannot understand these problems. Prof. Alan Brown does not subscribe to this view; he describes in his Ingleby lectures of 1948 the father of a young child supposedly suffering from "tummy-ache" rending the night air with its cries; the ignorant and ignored male observes, "If that were a puppy I'd say he was hungry and feed it."

Birmingham. B. S. B. WOOD.

LIVER EXTRACT FOR HERPETIC PAIN

SIR,—Dr. Christopher Howard's letter in your issue of Aug. 2 prompts me to write in support of his findings. My own experience has been that liver extract, apart from the relief of herpetic pain, can have a most beneficial effect on the whole course of herpes zoster. The response varies from one case to another, but I have yet to meet a case which has failed to respond in some degree provided injections are started as early as possible and repeated if necessary. At best, the results can be little short of dramatic, and it was a case of this nature that drew my attention to an interesting side-effect.

A middle-aged woman came to see me in the autumn, with an early typical herpes of the left loin. I gave her 2 ml. 'Anahæmin' which resulted in rapid relief of symptoms and disappearance of the local lesions. About a year later she asked me if the injection could have been responsible for her freedom from chilblains throughout the winter; she was normally a "martyr" to these, and had not enjoyed such comfort for years. A further trial injection seemed justified, and the result was again satisfactory.

I have since used liver extract for a number of chilblain cases. Again the response varies from one patient to another. Injections may have to be repeated in the more obstinate cases, but I have found no other form of therapy so rapid in its effect, the relief of irritation often becoming apparent in a matter of hours, and the healing of broken chilblains being much expedited.

Ashwell, Herts. J. H. MOYNIHAN.

SYRINGE-TRANSMITTED TUBERCULOSIS

SIR,—I think that one point in this subject, discussed in your annotation of July 5, has not yet received sufficient attention. Most people seem to agree that the tubercle bacilli enter from without and that they are carried by infected needles or syringes. The fact that these abscesses have become more common since the introduction of penicillin is partly explained by the use of the small rubber-capped bottle for penicillin. The cap is pierced with the needle when withdrawing the solution; and, as these bottles may be used for multiple injections, once the contents are infected an abscess may follow each subsequent injection. The point is, however, that this kind of bottle and rubber cap is nothing new—insulin has been kept in this way for years. Admittedly the number of penicillin injections given to children (in whom the majority of abscesses have developed) is larger than the number of insulin injections, but I cannot find a single report of a tuberculous abscess after an insulin injection. And diabetics are certainly not resistant to tuberculosis!

The use of the bottle instead of the ampoule does not explain everything. I think the basic point is this: the needles and syringes that carry tubercle bacilli are usually loaded with other germs as well, mainly gram-positive cocci, which are sensitive to penicillin. Inside the bottle the antibiotic exerts some sort of bacterial selection, and only the tubercle bacilli survive. When the solution is injected a tuberculous abscess ensues. When insulin or some substance other than an antibiotic is injected, a trivial pyogenic abscess occurs.

Novara Civil Hospital,

CLINICAL MEASUREMENT OF BLOOD-FLOW

SIR,—Few problems in experimental medicine and surgery have taxed the ingenuity of research-workers so much as the direct measurement of blood-flow in various organs, such as the kidney, heart, brain, and liver; and the use of so many different methods shows that a satisfactory solution has not been found.

All these methods suffer from such disadvantages as the necessity of severing blood-vessels, clotting of the blood in the glass connections and tubes, alteration of the hydraulic properties of the flow by the introduction of resistances, eddy currents, volume changes, and interference with the nerve-supply. Many are too complicated and unstable for clinical use.

I should like to describe a new and simple method.

If AB (fig. 1) represents a small known distance along a blood-vessel, say 1 cm., the speed of the blood can be determined by measuring the time taken by a given particle (P) to travel from A to B. The particle may be any harmless substance introduced into the blood-stream some little distance above A. It should differ from blood in some physical property, such as electrical conductivity, radioactivity, colour, refractive index, or density, which will enable it to be differentiated and picked up at A and B as it flows along in the blood-stream.

The actual way in which the arrival of this tracer substance first at A and then at B is recorded depends entirely on its nature. It may be done with a resistance bridge, a photoelectric cell, or in many other ways which will readily suggest themselves according to the physical property selected. Some methods will require the insertion of one or two fine needles into the vessel wall; in others more contact with the wall will be sufficient.

For example, an experiment was designed on the basis of the difference of electrical conductivity between blood and the tracer substance. Two extremely fine needles which just penetrated the lumen were used at A and B, and AB formed one arm of a resistance-bridge. Alternatively, only one needle (B) need be used, and the needle of the injecting syringe can serve as A; or the release of the syringe plunger can produce the starting impulse by some electrical coupling at the instant the tracer substance is released.

Fig. 2 shows the oscillograph recording obtained when an air-bubble was injected a little above A. Its passage is clear cut, and its speed can be measured absolutely accurately to the nearest $^1/_{100}$ second, for the tracing constitutes a modulated 50-cycle carrier wave and thus is self-timing. The lower tracing is an optional time-base with superimposed 1 second impulses.

Other substances tried were hypertonic and hypotonic saline, distilled water, very dilute organic acids, and oils; and all gave good deflections. The disadvantage of employing aqueous solutions is that unavoidable diffusion occurs which obscures the wave front and renders it less distinct. No matter which tracer substance is used and what receptor mechanism is employed to detect its passage, the aim is to get as sharply defined a wave front as possible. An ideal substance would be an innocuous liquid, more or less immiscible with blood, devoid of any tendency towards adhesion to the walls, and of a specific gravity approaching that of blood, but differing in some other physical characteristic. Some of the higher alcohols are under investigation, and octyl alcohol has given excellent results. I am carrying out further experiments with this method which will be reported later.

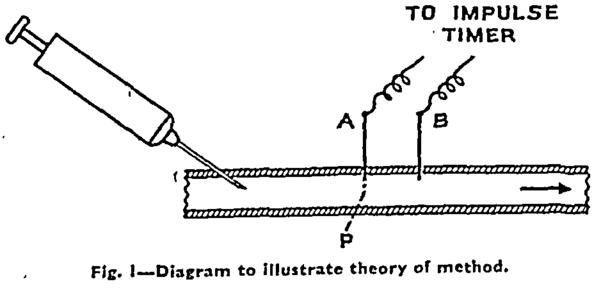

Fig. 1—Diagram to illustrate theory of method.

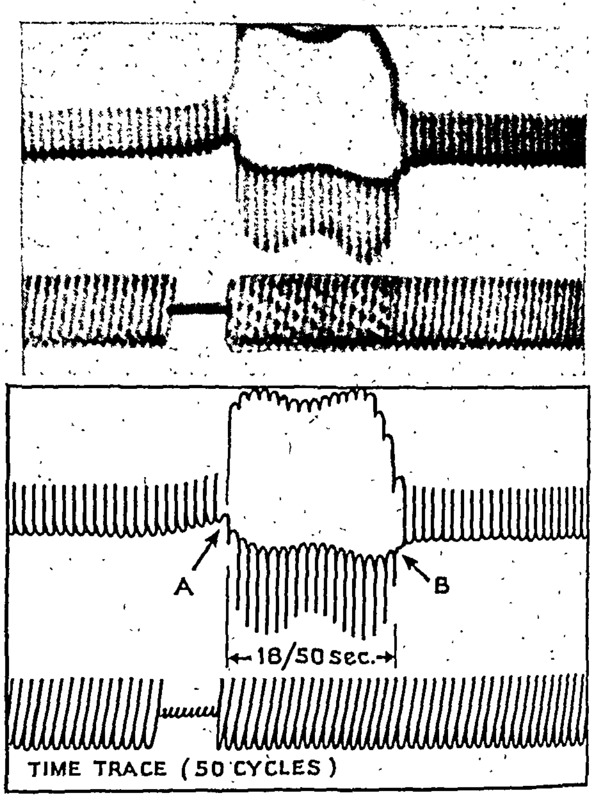

Fig. 2—Oscillograph recording of passage of air-bubble between 2 needles 1 cm. apart. Time of transit = $^{18}/_{50}$ sec. Speed of flow = 2·78 cm. per sec.

I am indebted to Prof. W. E. Underwood and Mr. P. Theron for their encouragement and for the provision of the necessary experimental facilities.

Johannesburg. ARTHUR SKOWRON.

PLEA FOR PSYCHOTHERAPY

SIR,—Dr. Marion Greaves (July 26) seems to be pleading for a wider application of psycho-analysis on Freudian lines.

At a time when psychiatry struggles for the acceptance of its terminology, an extension of such treatment seems unjustified. As she rightly stated, treatment must be preceded by correct diagnosis, and, I may add, based on scientific knowledge of the subject. Psychiatry is not yet a science; its principles and conclusions are purely hypothetical and empirical, and its methods are derived from medicine. She also admits that the body-mind relationship has so far been insoluble. How then can a correct diagnosis be reached? Although Freud did valuable work in mapping the human mind, his interpretations are too imperative and many of his *deductions* do not stand logical reasoning. The Roman Catholic Church has applied psycho-analysis for nearly 2000 years in the more agreeable and much less dangerous form of confession. Reactivation of dreadful past experiences can produce irreversible psychosis—a danger *not to be treated lightly*. Unfortunately we lack frank statistics from analysts about cures and failures.

To take another interesting aspect of the subject, there are no more scientific proofs *for* the existence of mind than there are *against* the existence of the soul. Can they be the same?

In my opinion this problem should be approached with more respect. Analysing the psyche without knowing its nature seems the equal of undertaking a major operation without anatomical knowledge. Freudian analysis should wait until we have more knowledge.

As Dr. Strauss said in his Croonian lectures (July 5 and 12), psychiatry is, from a scientific point of view, some fifty years behind medicine. So let us pass along the accessible way, proceeding from the lesser to the greater complex, and tackling the subject from the physical aspect. That was the path of progress for medicine and should be for psychiatry as well.

Barnsley Hall Hospital,
Bromsgrove. J. W. MULLNER.

HOSPITAL ADMINISTRATION

SIR,—One would imagine from the number of committees set up for the purpose that the medical profession was not without interest in hospital administration. What the present system lacks—and it is to this that I presume Dr. Bruce refers in his letter of Aug. 2—is some means whereby what might be called "administrative emergencies" are dealt with on the spot. The need for this varies in different hospitals; but it is generally agreed that it makes for smoother administration, and so "closely concerns the interests of the patients," if someone with a knowledge of medicine is willing to undertake this responsibility in addition to his clinical work.

London, S.W.1. J. R. M. WHIGHAM.

HYOSCINE IN TREATMENT OF SEASICKNESS

SIR,—On a long sea voyage recently I had the opportunity of observing the effect of hyoscine on fully developed seasickness. The patients were three women (aged 30–61) and four girls (one aged 11, the others under 3 years). The *l*-hyoscine hydrobromide was given as a powder in gelatine capsules or in water. The initial dose for adults was 0·5 to 1 mg. and that for children 0·25 to 0·5 mg.; maintenance doses of 0·5 mg. every 7 to 8 hours up to a maximum of 2 mg. in 24 hours were given to the adults, and the children were sometimes given a second 0·25 mg. after 8 hours. All patients were made to lie down for the first hour of treatment.

Fifteen bouts of seasickness were treated; with one exception all the patients were pale and prostrate, and on ten occasions they were vomiting, when treatment began. The drug was always retained. The children were soon up and about, and though the adults continued to have slight nausea they were able to take food and did not vomit. These observations suggest the *l*-hyoscine can cure or improve seasickness in women and children, and that large doses of this drug can be given repeatedly without ill effect.

Singapore. E. M. GLASER.

TUBERCULOSIS IN PREGNANCY

SIR,—I have closely observed a group of 28 tuberculous pregnant women with a follow-up period of more than three years. The following observations were made:

> 5 had an abortion in the first trimester of their pregnancy. Subsequently all of these women had an exacerbation of their disease. 23 bore the pregnancy well and had full-term normal deliveries; only 6 of these women had an exacerbation of their disease. From these results it would appear that abortion is more dangerous than continuing the pregnancy to full term. In my opinion pregnancy itself does not influence unfavourably the course of tuberculosis if the patient submits to appropriate and adequate treatment.
>
> It is of interest that 42% of women whose tuberculosis was diagnosed during pregnancy had aggravation of their disease; whereas only 20% of women whose tuberculosis was recognised before the pregnancy had aggravation. This, I feel, is due to earlier and more adequate treatment of the disease in the latter group.

In my opinion, the prognosis of tuberculosis in pregnancy depends on: (1) the extent and type of the lesions; (2) appropriate, adequate, and timely treatment; (3) the obstetrical course of the pregnancy. Only in rapidly progressive tuberculosis with severe toxicity should abortion be considered. It should be used only during the first trimester of pregnancy. In all other cases, whatever the form of pulmonary tuberculosis or duration of pregnancy, I recommend continuation of the pregnancy under close supervision and appropriate treatment. A difficult delivery is to be avoided, and the baby should be separated from the mother immediately after delivery.

I also suggest that all women should undergo radiographic examination of the chest before conception and periodically during pregnancy. Ideally, tuberculosis should be inactive for at least two years before pregnancy is permitted.

Athens, Greece. CONSTANTINE P. STAVROPOULOS.

FUNGUS INFECTIONS OF THE FEET

SIR,—Your annotation (June 7) on this subject indicates that the condition is difficult to treat effectively. It is certainly widespread, but for those living near the sea the following simple method will often prove effective:

> Allow the scrubbing action of sand particles to take away dead and sodden skin. At the same time the action of brine will help to rehabilitate the feet. Paddling in sea-water for an hour a day will enable the skin to regain its normal texture.
>
> Prevention of reinfection is also simple. All footwear should be disinfected. This may be done by rinsing with 1 in 8 'Cyllin,' and allowing the disinfected articles to lie twenty-four hours inverted to drain and dry. Clean socks daily are essential. Thorough daily washing of the feet with soap and water is equally important, and may not be omitted by those who are liable to fungus infection of the feet.

Prince Albert, Saskatchewan,
Canada. A. ROTHWELL.

SUCCINYLCHOLINE

SIR,—In view of the recent correspondence about succinylcholine, the following case may interest your readers.

A man, aged 58, who gave a history of angina pectoris for 3 years, underwent a partial gastrectomy for peptic ulcer. His weight was 140 lb., blood-pressure 150/90 mm. Hg, and Hb 94%.

The course of the operation was as follows:

12.23 P.M. Induction of anæsthesia with 0·5 g. of thiopentone, followed by 100 mg. of succinylcholine. Oral intubation with a cuffed tube, and administration of 20% oxygen in nitrous oxide. Intravenous saline drip started.

12.31 P.M. Spontaneous respiration established. 5 mg. of decamethonium iodide (C10) mixed with 25 mg. of pethidine hydrochloride into drip. Controlled respiration for 15 min., after which respirations were again spontaneous.

12.57 P.M. 3 mg. of C10 given. Spontaneous respiration continued.

1.7 P.M. 2 mg. of C10 given. Spontaneous respiration continued.

1.11 P.M. Saline drip changed to 500 ml. of 1 : 1000 lignocaine ('Xylocaine').

1.28 P.M. 100 mg. of succinylcholine given. Controlled respiration for 15 min. Respirations again spontaneous.

1.52 P.M. 3 mg. of C10 given. Assisted respirations for 3 min.

2.6 P.M. 50 mg. of succinylcholine given. Controlled respiration for 3 min. Immediately after this dose of succinylcholine, blood was substituted for the lignocaine drip which was almost finished, the patient having had 0·5 g. of lignocaine in 38 min. Diaphragmatic breathing returned within 3 min., but complete paralysis of the intercostal and abdominal muscles persisted.

2.20 P.M. Patient returned to the ward, maintaining himself on oxygen given through an endotracheal tube, with occasional assistance.

2.45 P.M. Patient given 10% carbon dioxide. Colour remained good with assisted respiration.

3 P.M. 6 ml. of nikethamide given into drip. No respiratory response, but fibrillary twitchings of both deltoids noted.

3.20 P.M. 6 mg. of neostigmine given into drip. Within 90 seconds the patient was breathing deeply, using intercostal and abdominal muscles. As was expected, he salivated freely, but was soon able to clear his throat himself. His subsequent recovery was uneventful.

During anæsthesia the patient received two doses of succinylcholine and three of decamethonium iodide from which he recovered spontaneously, indicating an adequate concentration of plasma cholinesterase. But he did not recover from the third dose of succinylcholine, despite a blood-transfusion, until after 6 mg. of neostigmine was given.

It should be remembered that after a long anæsthetic, or in debilitated subjects, failure to regain muscular tone may not necessarily be due to the persistence of a relaxant drug in the system. In patients who have previously responded normally to succinylcholine neostigmine may be used with benefit.

Northallerton, Yorks. J. SHEGOG RUDDELL.

SORE THROAT AND RHEUMATIC FEVER

SIR,—In your excellent leading article of July 12 you state, " to Coburn in the United States, and to Schlesinger and Sheldon in this country, goes the credit for bringing again to general notice the clinical relation of upper respiratory infection to rheumatic fever." It does not really matter who the credit goes to now that group-A, β-hæmolytic streptococcus has been accepted as causal agent, but the actual facts are these :

> Sheldon and I were working on the epidemiology of rheumatic fever about 1930 at Great Ormond Street and certain convalescent homes for rheumatic-fever patients. We were greatly helped and encouraged in these studies by J. A. Glover and Fred Griffith. It was Griffith who said to me, on studying our epidemiology charts, that he believed the infecting organism was a hæmolytic streptococcus, and it was he who typed those I found by his own method. Schlesinger's contribution was his observation of the silent period between the initial throat infection and the subsequent rheumatic-fever attack, or relapse, and the effect on the subsequent attack of salicylate if given during this silent period. This aspect was omitted from your article.

It is interesting to note also that Coburn's manuscript and those of Sheldon and myself[1] (both published the same day in THE LANCET as complementary papers) were in the press at the same time, both he and we having come to the same conclusion, though his studies were all carried out in America and ours in London. I think I can claim definitely to have been the first person on this side of the Atlantic to state in a paper that the hæmolytic streptococcus was *a*, if not *the*, infective factor in rheumatic fever.

Rotunda Hospital, Dublin. W. R. F. COLLIS.

Medicine and the Law

Fatal Injection of Sulphuric Acid

ON July 31 an inquiry was held in Glasgow into the death of a 13-month-old boy who died 9 days after a rectal operation.

The baby had been suffering from diarrhœa and later developed piles. He was admitted to hospital on May 31, and two days later an injection of what was thought to be absolute alcohol was made under an anæsthetic. A surgeon, who was asked to see the baby a few days later, said at the inquiry that the child's condition was inconsistent with alcohol having been administered. The tissues into which the fluid had been injected had been destroyed, and there was extensive inflammation spreading round to the groin and the abdominal wall, with severe swelling in the rectum. The bottle from which the fluid had been drawn was investigated, and it was discovered that the bottle, though it was labelled " absolute alcohol," did in fact contain 20% sulphuric acid.

The surgeon who gave the injection said in evidence that when the theatre sister handed him the syringe, he had not tested the contents. The appearance of the liquid had been consistent with that of absolute alcohol, and, even had he not been wearing a mask, he could not have told by smell whether it was sulphuric acid or not, because of the various other smells in the theatre.

The theatre sister said that she had filled the syringe from a bottle which had been received from the dispensary about a month before and which had been kept under lock and key until first used on the day of the injection. Sulphuric acid was never kept in the theatre.

The hospital superintendent said that on June 5, having learned that the baby was very ill and that there was doubt about the contents of the bottle, he went to the hospital pharmacy and examined the cupboard where the pure alcohol was kept. He had found a large green bottle marked " absolute alcohol," and beside it another bottle marked " sulphuric acid, 20%." Both bottles were coloured green and were the same size.

The two dispensers agreed that one of them must have filled the bottle, but neither could remember which. Asked how such a mistake could have happened, one replied that her attention might have been distracted by a telephone call or someone coming into the dispensary with a message.

Prof. John Glaister, professor of forensic medicine in the University of Glasgow, said that on June 21, with another doctor, he conducted a post-mortem examination. Death had resulted from rectal necrosis and peritonitis. Asked if he had any suggestion to make about ways of avoiding such mistakes, Professor Glaister said that bottles could be of different colours, and those containing acid could be corrugated. Bottles could be initialled by the dispenser after filling and labelling. The contents could be checked in the theatre or ward to which they were sent.

The jury returned a verdict in accordance with the medical evidence, adding a rider that " dangerous toxic substances and acids should be kept in distinctive bottles."

Hypnotist's Successful Appeal

At the end of March Miss Rains-Bath was awarded damages at Sussex Assizes against Mr. Ralph Slater, a stage hypnotist, for his conduct towards her during a demonstration at the *Brighton Hippodrome*.[1] The Court of Appeal has now ordered a re-trial of her claim in respect of the major item in the award.[2] The jury gave her £25 for a not very serious assault: he had placed his fingers on her neck and jerked her head forward; on this part of the case the award is to stand. They also gave her £1000 (and £107 special damages) for his alleged negligence; on this part of her claim the Court of Appeal found the trial unsatisfactory. The trial judge, it seems, was not properly informed of the issues, though one would suppose that the pleadings must have disclosed the particulars of the allegations of negligence on which she relied; he did not, it seems, adequately direct the jury. He directed the jury carefully, says Lord Justice Singleton, as to the nature of negligence and as to the duty of Mr. Slater in respect of the issues as the trial judge understood them. On the other hand he never directed the jury's attention to Mr. Slater's denial of having ever said that the demonstration was harmless. The Lord Justice could not find that the trial judge had suggested the following questions to the jury:

---

[1] Collis, W. R. F. *Lancet*, 1931, i, 1341. See also Collis, W. R. F. *Amer. J. Dis. Child.* 1932, 44, 785. Collis, W. R. F., Sheldon, W. *Lancet*, 1932, ii, 1261. Collis, W. R. F., Sheldon, W., Hill, N. G. *Quart. J. Med.* 1932, 1, 511. Collis, W. R. F. *Proc. R. Soc. Med.* 1932, 25, 1631. Collis, W. R. F. *Practitioner*, 1935. 134, 617. Collis, W. R. F. *Lancet*, 1939, ii, 817.

[1] *Lancet*, 1952, i, 725.

[2] *Times*, July 31, 1952.

> Had Mr. Slater implanted in the plaintiff's mind something of a frightening or terrifying nature?
>
> If so, was it something wrong and dangerous—in other words was it negligent?
>
> If so, had Mr. Slater taken sufficient steps to remove it?

There had been no direction that the measure of duty placed on Mr. Slater was that to be expected of one who practised as a stage hypnotist, and no higher.

It was, says the Court of Appeal, an unusual case; "no one could describe it as a strong one"; the medical witnesses must have found difficulty in connecting the plantiff's condition some 18 months after the occurrence with the occurrence itself, though there was some evidence on that point.

There were members of the public who read the result of the trial last March with a certain surprise. They will await with interest the fresh trial, reflecting perhaps that a good deal of money has been spent by the parties upon getting a decision and that this expense, through no fault of the parties, has been thrown away.

Obituary

EDWARD ROLAND GARNETT PASSE

B.D.S.Melb., F.R.C.S., D.L.O.

Mr. E. R. Garnett Passe, senior consulting aural surgeon to King Edward Memorial Hospital, Ealing, and aural surgeon to Wembley Hospital, who died on Aug. 1, had made a substantial contribution to the development of the fenestration operation for otosclerosis.

Garnett Passe was an Australian, and he took a dental qualification at Melbourne in 1926 before he came to this country to study medicine. He had intended to take his medical course at Glasgow, but the chance recommendation of a fellow passenger on the boat coming over to this country deflected him to London, and he qualified from the London Hospital in 1929. One of the house-appointments he held at the London Hospital was that of house-surgeon to the aural department, and there his interest in otology grew, so that he gave up his original intention of returning to practise in Australia and remained in this country to take further qualifications in his chosen specialty. After holding a house-appointment at the Central London Throat, Nose and Ear Hospital he obtained the D.L.O. in 1931 and the F.R.C.S. in 1936. Later he was appointed first assistant and registrar at the London Hospital. Soon afterwards he joined the staffs in the aural department of the King Edward Memorial Hospital, Maida Vale Hospital, Hounslow Hospital, and Wembley Hospital. During the late war he served with the R.N.V.R. with the rank of acting surgeon commander.

Despite a busy and successful practice he still found time for research on clinical problems. Since the war his main work had been the development of the fenestration operation for otosclerosis, and he was one of the group of British surgeons who have practised this procedure. Several times of recent years he was invited abroad to demonstrate his technique for this operation. Lately he had also become interested in the effect of the sympathetic nervous system on conditions such as Ménière's syndrome, tinnitus, and nerve deafness; and at the time of his death he was studying surgical methods for dealing with these conditions. He had performed several dorsal sympathectomies, and it was a measure of his surgical ability that he could perform these operations himself and need not hand them over to a neurosurgeon. In the same way during the war he often turned his hand to general surgery when occasion arose.

A colleague writes: "Garnett Passe was a man of quiet personality who was tremendously keen on his work. A loyal friend and colleague, he was particularly kind to juniors, and he would go out of his way to help a former assistant. On his winter sports holidays he showed the same quiet determination to deal with the job in hand—though this might be a rather nasty-looking steep run. It is a tragedy that his career should end so early, for he was capable of so much and there was so much that he wanted to do."

HAROLD ETTRICK MOORE

O.B.E., M.B. Manc.

Dr. H. E. Moore, who died on Aug. 6 at his home at Crewe, will be remembered for the years of service he gave to the railway community and for his work as an adviser on reablement to the Navy and the Air Force during the war.

He was born in 1878, at Silverston, Northamptonshire, where his father, the Rev. George Moore, was vicar. The family later moved to Denham Vicarage, near Bury St. Edmunds, where he spent his boyhood. He was educated at a preparatory school kept by his uncle, near Alnwick, Northumberland, and later, after a short period at Denstone College, won a scholarship to King's School, Ely. The family moved to Lancashire on the appointment of his father to Parkfield Vicarage, Middleton, Lancashire, and Moore began his medical studies at Owens College, graduating M.B. in 1904. At the university he was an outstanding athlete and he captained both cricket and rugby. He played for three years in the Lancashire county rugby side, and he was awarded a North of England cap. He was also a first-class golfer.

Moore's first appointment was at Manchester Royal Infirmary as house-surgeon to the late Sir William Thorburn. After holding other resident appointments at Salford Royal Hospital, Withington Hospital, and the Mental Hospital at Ayr, he worked as an assistant in a general practice in Oakham, and in 1908 he started in practice on his own at Bollington, Cheshire. He gave up this practice after a year to join his uncle in practice at Stourport-on-Severn, Worcestershire. In 1915 he joined the R.A.M.C. He served in Gallipoli where he was attached to the hospital on Cape Hellas. After the evacuation he served in the Hospital Ship *Asturias*, and when she was torpedoed in the English Channel he was one of the last to leave the ship.

On demobilisation he returned to Stourport to find most of his practice gone. He therefore took an appointment with the Ministry of Pensions as D.C.M.S. at Newcastle upon Tyne and later at Darlington. But his natural bent was towards active surgical practice, and in 1922 he was appointed surgeon to the London and North Western Railway Works Hospital at Crewe, his old chief, Sir William Thorburn, being at that time consulting surgeon to the L.N.W.R. Moore immediately began to develop and modernise the hospital, which undertook all the casualty work and traumatic surgery for the Crewe works and the other railway staff in the locality. From 1922 till his retirement in 1949 his life and work were spent in the care of the railway workers. He gave the strictest attention to detail, supervising the treatment of even trivial injuries himself, and he obtained excellent results.

He was appalled by the wastage and length of incapacity of many workmen's compensation cases, and he made these his special study. He tried his new ideas of active reablement and movement at first with a small number of cases. Later, convinced that his ideas were sound—and he was a man of such integrity that he was not easily convinced—he persuaded the L.M.S. Railway Company to build an extension to the Crewe Hospital with a large gymnasium and physiotherapy rooms for rehabilitation treatment, where patients not only from the Crewe area but also from other parts of the railway system were treated.

Owing to Moore's modesty and shyness, this pioneering work on reablement is not as well known as it should be; but in the orthopædic world it was recognised, and, with the coming of war in 1939, Moore was appointed civil adviser in rehabilitation to the Royal Air Force and later to the Royal Navy. He played a vital part in developing the reablement schemes for both these services; in recognition of this work he was appointed O.B.E.

After the war he continued in active practice as surgeon to the Accident Hospital at Crewe, and in 1947 he was appointed acting chief medical officer of the L.M.S. Railway.

He is survived by his wife, two sons, and one daughter.

DR. LESLIE CUNNINGHAM

A surgical colleague writes: "I shall always remember Leslie Cunningham as a first-class physician upon whose services I might call with confidence and without hesitation at all times. He believed in the closest coöperation between the physician and surgeon: he did not hesitate to advise operation in the appropriate case, nor to seek the views of his surgical colleagues if in doubt. He was exceptionally successful in dealing with difficult post-operative cardiac or pulmonary complications.

"Although he practised as a general physician, he had special interests. In his earlier years he had done research for the Liverpool Cancer Research Organisation, and he published work on the toxic effect of lead and on tissue metabolism. Cardiology, however, had a greater attraction, and one of his earlier appointments was that of medical officer in charge of the cardiographic department at the Northern Hospital. No doubt the frequent association of thyroid and cardiac disorders led to his closer study of thyroid disease and ultimately to the formation of a thyroid clinic at the Northern Hospital. Hospital commitments and private practice made heavy calls on his time; for his quiet, helpful, unassuming, and always friendly manner appealed alike to doctors and patients.

"He was a good teacher and he was always popular with the students, who realised his worth. Both his house-physician and registrar appointments were highly prized. The high esteem of the nursing staff was well expressed by one of his ward sisters on the day he died: 'How good he was to us and how we shall miss him!' He leaves behind many friends—doctors, nurses, and patients—who will echo these words."

Appointments

BATE, J. G., M.B. Edin.: pathologist, St. Mary's Hospital and Princess Louise (Kensington) Hospital for Children, London.
CURRIE, J. D., M.B.: asst. psychiatrist, Pewsey Mental Hospital, Wiltshire.
DAVIES, G. D., M.B. Lond., D.M.R.: consultant radiologist, Rhymney and Sirhowy Valleys H.M.C., Wales.
DAVIES, I. M., M.R.C.S., D.P.M.: consultant psychiatrist, Pen-y-Val Hospital, Wales.
GARSON, R. A., M.R.C.S., D.I.P.: asst. pathologist (S.H.M.O.), Halifax group of hospitals.
GRACE, R. F. T., M.D. Edin., M.R.C.P.: assistant (consultant status), department of psychological medicine, National Hospital, Queen Square, London.
HOLME, V. P., M.B., D.OBST.: asst. M.O. (maternity and child welfare), Coventry.
HOLMES, P. J., L.R.C.P.I.: superintendent, Sub-Regional Sanatorium, Ardkeen, co. Waterford.
MASTERS, P. L., M.D. Lond., D.C.H.: pathologist, St. Mary's Hospital and Paddington Green Children's Hospital, London.
NICHOLSON, HOWARD, M.D. Lond., F.R.C.P.: asst. consultant physician, Brompton Hospital, London.
PRINCE, G. S., M.B. Dubl., M.R.C.P.I., D.P.M.: part-time psychiatrist (consultant), Woodberry Down Health Centre.
THOMAS, ELIZABETH, M.B. Glasg.:
ZALESKI, W. A., M.B. Polish Sc : asst. psychiatrist, Pewsey Mental

Manchester Regional Hospital Board:

BOLTON, HAROLD, M.B. Manc., F.R.C.S.: consultant asst. orthopædic and accident surgeon, North Manchester hospitals, main duties at Ancoats Hospital.
COVELL, N. A. G., M.CH. Lpool, F.R.C.S.E.: consultant asst. orthopædic and accident surgeon, Preston and Chorley hospitals.
CULLEN, C. H., M.CH. Belf., F.R.C.S., F.R.C.S.I.: consultant orthopædic surgeon, orthopædic and accident services in the North Manchester hospitals, and Booth Hall Children's Hospital.
HARRIS, RONALD, M.C., M.D. Leeds, D.PHYS. MED.: consultant physical medicine), Devonshire
., F.R.C.S.: consultant asst. and district hospitals.
asst. venereologist, St. Luke's Clinic, Manchester.
WINSTON, M. E., M.B. Edin., F.R.C.S.: consultant asst. orthopædic surgeon, Bolton and district hospitals.

South Western Regional Hospital Board:

LINDSAY, IAN, M.B. Edin., F.R.C.S., F.R.C.S.E.: surgical registrar, Bath group of hospitals.
MCSWINEY, M. J., M.B. N.U.I.: asst. anæsthetist, Bath clinical area.
NEVE, C. R., M.B. Lond., F.R.C.S.: senior surgical registrar, Bristol clinical area.
NEVIN, H. M., M.A., M.B. Dubl., D.P.H., D.T.M. & H.: asst. clinical pathologist, North Gloucestershire clinical area.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital p otherwise stated. Canvassing disqualifies, but visit the hospital by appointment.

Notes and News

THE SITUATION OF THE MENTAL HOSPITALS

OF all patients, those with disorders of the mind might be expected to profit most from rest and quiet; and it is the great misfortune of our mental hospitals that these are the forms of therapy which they are least able to offer. Last year, as the annual report of the Board of Control for 1951[1] tells us, the number of patients in mental hospitals in England and Wales rose to 135,626, a gain of 436 on the previous year. For many years now this figure has been rising, and even our vast service is too small to cope with the demands on it. Accommodation in terms of bedspace, the report says, was for 123,906 patients; but not all accommodation was in use: 1071 beds were still diverted to other services, 1748 could not be used because there were no nurses to staff them, and 1585 beds were unoccupied because the wards were being put in order. In all there was a deficit of no less than 16,124 beds. Of course this is only a manner of speaking, for, in fact, beds must have been found for every one of the 135,626 patients; and what this meant in terms of overcrowding, noise, and misery only the nurses, spread thinly among them, could fully report. Recruitment in other branches of nursing has reached a peak, but in mental nursing the number of student nurses is still declining, though there has been some increase among trained nurses. Nursing assistants and part-time staff have given some help, but the ratio of male nurses to patients is 1 to 5·5, and of female nurses 1 to 7·1. "The remedy is not yet in sight," says the report, not altogether helpfully, "but the problem is one which is constantly before all concerned."

The need for a solution is all the more urgent because patients are beginning to show a livelier trust in the resources of the mental health service. Many more are being admitted as voluntary patients, though the report notes that practice varies in different parts of the country: a few hospitals receive more than 90% as voluntary patients, while others take almost half their patients under certificate. The social importance of avoiding certification is considerable, and if patients see a psychiatrist before they are admitted to hospital, he can explain this to them. Besides, it is easier to treat a coöperative voluntary patient than a resentful certified one. Outpatient centres staffed by the doctors who also treat the inpatients have done much to foster early treatment, and the board find that where outpatient departments are active the voluntary admissions tend to be high. Fortunately such departments are increasing in number: in 1939 there were only some 200, but there are now almost twice as many. With so much gained, and every promise of further advances, we shall be foolish if we forget that mental treatment depends finally for success on adequate nursing. The problem of recruiting mental nurses needs special study.

PRESCRIPTIONS IN JUNE

THE new charges for medicines, dressings, and appliances were introduced on June 1 this year; and figures issued by the Ministry of Health show that in England and Wales the number of prescriptions declared as having been submitted during that month was 14,416,800, representing a decrease of 15·57% on the number in June, 1951. The number of forms in June this year was 8,545,000, representing a decrease of 20·4% on the number in June, 1951; and the number of prescriptions on each form averaged 1·69, compared with 1·57 in the previous June. The proportion of forms on which one or more of the prescriptions cost over 5*s.* net was about 24%, compared with 20% in June, 1951. The estimated average total cost per prescription was about 1¼–1½*d.* higher in June this year than in the previous month, judging by the findings from a 1% sample of chemists; the comparable increase between May and June, 1951, was just under 1*d.*

YOUNG CONVALESCENTS

Dr. Frank Falkner's account of his inquiry into the care of convalescent children in this country, in the United States, and in Switzerland, which he summarised in our issue of March 29, has now been published in full under the title of *The Convalescent Child.* Copies may be had from the Department of Child Health, Alder Hey Children's Hospital, Liverpool, 12.

TUBERCULOSIS ERADICATION AREAS

The Ministry of Agriculture have declared the following two districts to be tuberculosis eradication areas:

Counties of Cardigan and Carmarthen (except the Bettws Mountain district) and part of Pembrokeshire, in Wales.

Counties of Ayr, Dumfries, Kirkcudbright, Renfrew, and Wigtown, and parts of Argyll and Bute, in Scotland.

After Oct. 1 all herds in these areas will be tested and reactors will be slaughtered, with payment of compensation. When bovine tuberculosis has been eradicated, they will be declared attested areas.

STATISTICS OF CAUSES OF DEATH

The World Health Organisation Centre for Classification of Diseases has prepared a booklet[1] designed to indicate the difficulties encountered in maintaining continuity of statistics of causes of death, and to show how those difficulties may be overcome. Rearrangements of the International List, changes in the form of death certificate, and the many different ways in which the principal cause of death may be selected for tabulation from several causes stated on the certificate have all made it increasingly difficult to compare figures accurately. These difficulties are partly illustrated in a section devoted to statistics of diabetes, where it is shown how the rigid rules used in the past for selecting the principal cause placed too much weight on diabetes as the cause of death—an emphasis out of proportion to its actual significance as a fatal disease. These rules necessarily produced statistics of diabetes which could not be compared with those of countries which relied on the opinion of the certifying doctor as to the principal cause of death. This publication is intended to help those who prepare and study the trends in death-rates from separate causes. Methods of preserving the continuity of statistics of mortality-rates are discussed and examples of possible situations given.

HOSPITAL FOR TROPICAL DISEASES, LONDON

Attention was lately drawn in Parliament[2] to the help which this London hospital now offers to patients with tropical diseases in whatever part of the country they live. Since it moved last year into its new building in St. Pancras Way, N.W.1, its accommodation includes 68 beds, an outpatient department, and pathological laboratories. It is intended that the hospital, as part of the National Health Service, should be a consultative centre for the specialised treatment of tropical diseases, and any general practitioner in any part of the country can send a patient direct to the hospital, where there is a comparatively short waiting-list for inpatient treatment. The Ministries of Health and Pensions are particularly anxious that these facilities should be known to Servicemen and pensioners.

TREATMENT OF RABIES

A new development in the treatment of rabies was described at a conference sponsored by the World Health Organisation and held at the Pasteur Institute in Coonoor, Southern India.[3] A serum, prepared from the blood of horses whose immunity to rabies virus has been raised by repeated vaccination, is under trial in Iran. It is being given to people who have been attacked by rabid wolves. Incidentally, it seems that a bite from one of these animals is more often the cause of a fatal infection than the bite of an infected dog. Hitherto, treatment has involved daily vaccination for 2–3 weeks with a vaccine usually obtained from the brain of an infected sheep. But the method is not altogether satisfactory; for one thing, the use of the vaccine occasionally promotes the formation of demyelinating antibodies which may cause paralysis. Though no results of the trial have yet been reported, there are good hopes that the serum may prove a simpler and safer means of reducing the mortality of rabies, which is responsible for about 3000 deaths every year in India alone. The serum is not yet available commercially.

University of Oxford

On Aug. 2 the degree of B.M. was conferred on C. T. M. Wilson and E. H. Jellinek.

University of London

At recent examinations the following were successful:

M.D. Branch I (medicine).—M. W. Arthurton, D. W. Barritt, D. C. Beatty, Brian Creamer, F. E. Dische, D. D. Gellman, E. W. Hughes, C. B. Ingor-Willey, A. H. Levy, Joyce J. P. Lomas, Mohamed Ajawad Macan-Markar, D. Y. Mackenzie, R. G. Moore, P. W. Nathan (*mark of distinction*), James Parkyn, M. G. Philpott, A. E. A. Read, I. P. Ross, G. W. Scott, H. T. N. Sears, D. G. H. Sylvester, Alfred Wiener (*mark of distinction and university medal*), Eirian Williams, T. C. P. Williams.

M.D. Branch II (pathology).—J. V. Dacie, L. R. Davis, J. H. O. Earle, H. V. J. Fernando, Harry Greenburgh, T. D. S. Holliday, A. C. Hunt, Margaret P. Jevons, B. W. Meade, W. D. Ratnavale, J. H. Shore, J. M. Talbot, Phyllida M. M. Thornton, J. R. B. Williams, T. B. Williamson.

M.D. Branch III (psychological medicine).—A. A. Baker, R. A. Hunter, E. J. Rich, J. D. Richardson, Ebben Roderic-Evans.

M.D. Branch IV (midwifery and diseases of women).—A. C. Barthels, D. P. Cocks, G. M. Evans, C. M. Flood, G. T. Hammond.

M.D. Branch V (hygiene).—L. J. Clapham, N. R. E. Fendall, Kathleen M. Harding, G. R. Holtby, Mary M. E. Rutter, J. F. Skone, M. D. Warren.

M.D. Branch VI (tropical medicine).—J. R. Harries.

M. S. Branch I (surgery).—J. W. P. Gummer, R. E. Horton, P. G. Large, K. W. Martin, A. J. H. Rains.

M. S. Branch III (ophthalmology).—H. N. Reed.

D.M.R. (diagnosis).—A. T. Broadbridge, R. J. Callander, David Datt, J. J. Geere, Victor Roseverne.

D.M.R. (therapy).—K. A. Newton, R. C. S. Pointon, L. C. Robson, Jean K. M. C. Wilson.

Mr. H. A. B. Simons, PH.D., has been appointed to the readership in physics at the Royal Free Hospital School of Medicine from Oct. 1.

University of Birmingham

Dr. P. H. Davison has been appointed clinical lecturer in medicine. The title of research fellow has been given to Dr. C. N. D. Cruickshank of the department of experimental pathology.

On July 5 the following degrees were conferred:

M.D.—F. G. W. Marson, H. W. Pooler.

M.B., Ch.B.—Christine C. Wade (with second-class honours); J. G. Ball, Geoffrey Baum, W. G. C. Bearcroft, Graham Beaumont, L. A. W. Bellamy, Beatrice W. Boulton, *P. A. Bramley, Iona M. Brereton, J. R. Brown, Michael Cooke, N. F. D. Cooper, G. H. C. Daley, O. W. Deacon, Dennis Dean, J. M. Dolphin, H. A. Ellis, Lucy M. Ellis, D. I. Ferguson, H. W. Goldfarb, R. N. Gunness, R. J. Halpin, Joan E. Hancock, Kenneth Harrison, R. C. Hartley, Margaret A. Hartshorne, Betty D. Heap, Laurence Henry, E. R. Hitchcock, B. D. Hodge, Jane C. Iles, Barry Ingham, G. H. Jeavons, Thelma D. Johnson, Olive G. Jones, Edward Kinnear, R. C. Lambert, *Judith M. Leather, C. G. Lloyd, Patricia M. Lumb, Ursula R. Mindelsohn, J. T. F. Morrall, G. A. I. Namsoo, Cecile E. Needham, Kathleen M. Neville, C. D. Oakley, J. R. Owen, J. S. B. Preece, G. J. Rice, *E. J. Rix, D. P. W. Roberts, G. G. Roberts, C. R. Salisbury, J. L. Skinner, E. A. Smith, Jean G. Smith, J. H. Smith, A. T. Spencer, K. A. Tomlinson, Meriel F. Underwood, D. H. Wadelton, Desmond Watton, H. E. Wells, Cleon White, George White, H. E. Wilson, R. G. Woodwards, Howard Young.

* In absentia.

Institute of Psychiatry

A two-year postgraduate course in psychiatry will begin on Oct. 6 at the Maudsley Hospital, Denmark Hill, London, S.E.5. Further particulars may be had from the dean of the institute at the hospital.

Chartered Society of Physiotherapy

The annual congress of this society is to be held at St. Pancras Town Hall, Euston Road, London, N.W.1, from Sept. 18 to 21. The speakers will include Dr. T. F. Main, Dr. J. B. Mennell, Dr. A. T. Richardson, Mr. R. Guy Pulvertaft, Dr. Ian Curwen, Mr. Terence Cawthorne, Dr. William Morton, and Dr. W. S. C. Copeman. Further particulars may be had from the secretary of the society, Tavistock House (South), Tavistock Square, London, W.C.1.

Committee on Venereal and Treponemal Infections

At their recent meeting in London this expert committee of the World Health Organisation elected Dr. G. L. M. McElligott (Gt. Britain) chairman, and Dr. M. Soetopo (Indonesia) vice-chairman. Since the committee last met in 1949, over 5 million people have been tested and over 2 million treated in demonstration and mass control campaigns supported by W.H.O. and Unicef.

Medical Women's Federation

The federation is to hold a congress in London from Oct. 31 to Nov. 2, to celebrate the 35th anniversary of its foundation. During the congress Dame Hilda Lloyd will deliver the Christine Murrell lecture, on Domiciliary Midwifery. There will also be a discussion on the Care of the Child in the National Health Service. Application for tickets should be made to the secretary of the federation, Tavistock House (North), Tavistock Square, London, W.C.1.

Increased Family Allowances

Arrangements for paying the increased family allowances to more than three million families are announced by the Ministry of National Insurance. The allowance goes up from 5*s*. to 8*s*. a week from Sept. 2 at an extra cost to the Exchequer of £39 million a year.

King's College Hospital, London

Messrs. Boots Pure Drug Company have renewed for a further seven years the deed of covenant under which they have, since 1945, paid £1000 a year to the diabetic research fund of this hospital. This subscription has enabled a new technique to be developed for the estimation of insulin in plasma.

Medical Conference in Jerusalem

A conference of Jewish doctors was opened in Jerusalem on Aug. 10. The programme includes a discussion on medical problems arising from the mass immigration of Jews to Israel. The British delegation of 30 doctors is headed by Dr. Eustace Chesser.

London Hospital Old Students' Dinner

Notices of this dinner, which is being held on Oct. 9, have now been sent to all Old Londoners whose addresses are known. Anyone who has not received a notice should write to the secretary, London Hospital Medical College, Turner Street, E.1.

Society for the Study of Addiction

The society will meet at 8 P.M. on Aug. 26 at 11, Chandos Street, London, W.1, when Dr. Francis T. Chambers, jun., of the Philadelphia Hospital Institute will deliver a lecture on the Analysis and Comparison of Three Treatment Measures for Alcoholism: Antabus, the Alcoholics Anonymous Approach, and Psychotherapy.

New Blood-transfusion Centre

On Aug. 7 Mr. Iain Macleod, the Minister of Health, opened the new North London Blood Transfusion Centre at Deansbrook Road, Edgware, Middlesex. The centre has been built by the North West Metropolitan Regional Hospital Board, at a cost of £45,000, out of their normal capital allocation. Till now the North London Blood Transfusion Centre was at New Barnet where it used a converted first-aid post as temporary premises. Mr. Macleod made a special appeal to young people to join the National Blood Transfusion Service. "If the future of the service is to be safeguarded," he said, "the younger generation must play their part to an even greater extent than they do at present." The importance of blood-transfusion in modern medicine, he added, was shown by the steady increase in the number of donations, which in England and Wales had now reached some 600,000 a year.

National Ophthalmic Treatment Board Association

This association held its 23rd meeting on July 18. It was reported that a great deal of work has been done by the medical appointments subcommittee in dealing with appointments to N.O.T.B. medical eye centres, and monthly meetings have been necessary. After a discussion of the report of the Crook Committee, it was agreed that certain recommendations should be made by the representatives of the association at the Ophthalmic Group Committee meeting on July 19 to ensure that the proper functions of ophthalmic opticians were clearly defined and to emphasise the great care needed in the composition of the proposed General Optical Council. The report on Future Eye Services was re-examined in the light of the Crook report, and, apart from the strengthening of two of the paragraphs, this report is being submitted unchanged to the Ophthalmic Group Committee. The need for an early upward revision of the sight-testing fee is to be emphasised.

The following is an extract from a Ministry of Health letter in reply to a point raised by the association:

> "We have always advised Ophthalmic Services Committees that there is nothing in any of the regulations made under the National Health Service Acts to prevent a general medical practitioner from supplying a patient with the name of either an ophthalmic medical practitioner or an ophthalmic optician provided that no attempt is made to conceal from the patient the fact that the patient has a free choice in selecting an ophthalmic medical practitioner [illegible] to test his sight.
>
> "As [illegible] on the back of Form O.S.C.1 clearly informs [illegible] purpose of having his sight tested he may [illegible] ophthalmic medical [illegible] has undertaken to provide supplement [illegible] under the National Health Service."

Consultants' Prescriptions

In Northern Ireland the Hospitals Authority has decided that consultants shall not issue prescriptions to outpatients referred to them by general practitioners. In a letter to hospital management committees, described in the Irish edition of the *Sunday Express* (Aug. 3), the authority gives the following reasons for its decision: (1) the issue of prescriptions by consultants tends to deny the practitioner his right to decide whether he will accept the consultant's advice; (2) this practice has proved wasteful; and (3) occasionally it discourages patients from visiting their doctors on return from hospital. According to the *Sunday Express*, some consultants have pointed out that the new arrangement may cause hardship to patients coming from remote districts.

A Health Centre for Sheffield?

A further attempt is to be made to organise a health centre in Sheffield. The proposal was turned down in 1950 by the local medical committee, on the ground that they could not guarantee that the centre would be fully manned by them. Last April the Ministry of Health was approached by Sheffield's town clerk with a request to convene a conference of all interested parties "to survey the problem anew, and without any reference to what has previously transpired." The city council was anxious to see the scheme working, and felt that circumstances were now different. At the Ministry's request, the executive council sought the comments of the local medical committee, which asked in what way the circumstances were different and more favourable. The town clerk replied that the city council had watched later developments in establishing health centres, some of which had been approved by the Minister. The council hoped that the further experience gained by the Minister might help in Sheffield if a conference were convened. The local medical committee have now expressed their willingness to take part in the conference, while not agreeing that circumstances are more favourable.

The executive council has also decided to join a conference, proposed by Sheffield regional hospital board, of representatives of local authorities, executive councils, and hospital management committees, to discuss coördination of all the branches of the National Health Service.

The address of the Medical Practices Committee is now 3, Deans Yard, Westminster, London, S.W.1 (tel.: Abbey 2357–58).

The British Standards Institution (24, Victoria Street, London, S.W.1) has prepared a draft standard for theatre-stretcher trolleys (CO[M]3318), and comments on it should reach the institution before Sept. 12. A revised standard for density bottles (B.S.733: 1952) has been published.

Births, Marriages, and Deaths

BIRTHS

GOULDING.—On July 31, at Guy's Hospital, London, to Molly (née Fowler), wife of Dr. Roy Goulding—a son.

HARLAND.—On Aug. 5, at Kachhwa, India, to Dr. Grace Harland (née Mellows), wife of the Rev. R. P. Harland—a daughter.

LORD.—On Aug. 7, at the County Infirmary, Louth, to Reda (née Williamson), wife of Dr. W. J. H. Lord—a son.

MARRACK.—On Aug. 2, at the London Hospital, to Pat (née Franklin), wife of [illegible] daughter.

NORMAN.—On Aug. 7, a [illegible] London, to Elisabeth (née Roosegaarde [illegible] r. A. P. Norman—a son.

STEIN.—On Aug. 5, at Old Court Clinic, W.5, to Lore (née Rachwalsky), wife of Mr. Gerard Stein, F.R.C.S.—a son.

MARRIAGES

ABERNETHY—DENNIS.—On July 25, Barclay Chivas Abernethy, M.B., of Aberdeen, to Isobel Ellen Dennis, M.S.R., of Aberdeen.

BUTCHER—BORDER.—On Aug. 9, at West Wickham, Kent, Anthony Sidney Fairbank Butcher, M.B., to Peggy Elizabeth Border, S.R.N.

CAMERON—BURGE.—On Aug. 2, at Braunton, Devon, Michael Cameron, M.B., to Enid Mary Burge.

MEASDAY—RANDALL.—On Aug. 9, at Woldingham, Surrey, Brian Measday, M.B., to Jean Margaret Randall, M.B.

DEATHS

BANNISTER.—On Aug. 5, at Morwenna, Lidden, Penzance, Marmaduke Bannister, M.D. Lond., formerly of Blackburn, aged 86.

GRUNBAUM.—On Aug. 2, Lionel Grunbaum, M.A., M.B. Camb., M.R.C.P., of Clifton Hill, London, N.W.8.

LEE.—On Aug. 9, at Muswell Hill, William Edward Lee, M.D. Lond., F.R.C.S., aged 81.

McWHAN.—On Aug. 6, at Cheeklaw House, Duns, Berwickshire, Andrew Alexander McWhan, M.B., B.SC. Glasg., D.P.H.

MUNRO.—On Aug. 4, at Denham Leys, Quainton, Bucks, John Douglas Ross Munro, M.D. Edin., aged 82, late of Nantwich, Cheshire.

RECENT TRENDS IN THE TREATMENT OF PULMONARY TUBERCULOSIS*

Causes of the Fall in Mortality

(F. A. H. S.)

THAT there has been a continued decline in mortality from tuberculosis is generally known: it has been evident since the figures were first recorded a hundred years ago. The two brief exceptions occurred in the major wars.

The comparative mortality index (C.M.I.), defined in the following formula, provides a useful method of assessing the change year by year.

If m is the death-rate at a particular group of ages, and r is the ratio of the population at those ages to the total population at all ages, in the relevant year; and if m' and r' are corresponding values for the base year 1938, then

$$\text{C.M.I.} = \frac{\sum m \, \frac{(r + r')}{2}}{\sum m' \, \frac{(r + r')}{2}}$$

Fig. 1 illustrates the almost steady decline of the C.M.I. It is easy to read into this curve the end of a long declining epidemic wave and to speculate on its continuation. Thus there is the suggestion of an improvement in the rate of decline after 1933: but is this because social and economic conditions were improving faster than before, or because methods of treatment had begun to make some impression on the incidence of the disease? Despite the unemployment prevalent at that time, the general advance in living standards was probably responsible; certainly it is unlikely that methods of medical treatment before 1933 lowered national mortality-rates substantially. Then, is the fall from 1933 to 1938 more rapid than that of previous years? If so, medical treatment may indeed have begun to have some effect; and some other factors point this way—notably the decline in tuberculous laryngitis and enteritis.

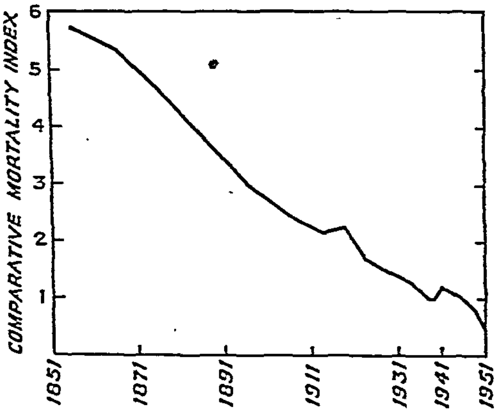

Fig. 1—Comparative mortality index, 1851–1951.

If the C.M.I. is plotted on a logarithmic scale, the *rate of change* can be more easily detected (fig. 2). From 1860 to 1933 the curve is almost a straight line—i.e., there is a constant rate of decline. Then the rate of change accelerates somewhat, but the war prevented a continuation of this trend.

Tuberculous laryngitis has shown a noteworthy fall in incidence. Formerly common, it is now becoming rare; we see it in less than 1% of patients now admitted to Clare Hall, and Professor Ormerod (1950) has reported a similar fall at Brompton Hospital. This fall began about twenty years ago, and a similar change has been noted in tuberculous enteritis. There seems reason to believe that the decline in these complications may depend partly on a more determined attack on pulmonary tuberculosis by collapse therapy: certainly it began long before chemotherapy was used. Does this link up with the accelerated fall in the C.M.I. which began about 1933?

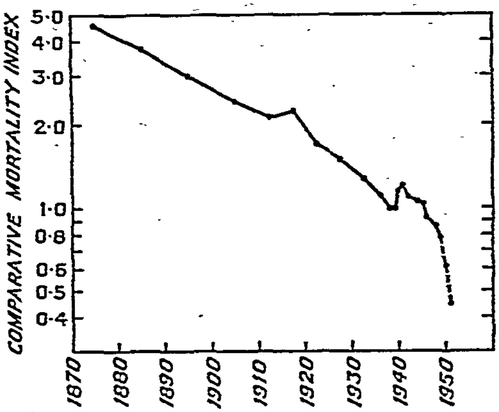

Fig. 2—C.M.I. since 1870, plotted on a logarithmic scale. Index for 1938 arbitrarily chosen as unity. Figures for all years till 1949 from the reports of the Chief Medical Officer of the Minister of Health. The figures for 1950–51 are an estimate based on the recorded mortality from pulmonary tuberculosis.

If recent treatment is proving more efficient in reducing the national mortality-rate from tuberculosis, this should be reflected in the rate of decline. An interesting fall in mortality during the last two or three years (fig. 2) has been concurrent with two important developments.

First, efficient chemotherapeutic agents have been introduced. Streptomycin, assisted by *p*-aminosalicylic acid (P.A.S.) is now used widely, and whatever may be the long-term effect it seems likely that these drugs, during the last two years, have prolonged life in many patients. If the effect is merely to prolong life for a few years the rate of change in the C.M.I. may shortly become slower; if a more permanent gain has been achieved we may expect it to continue at its present rate.

The second important development has been the strengthening of the tuberculosis service. Modern methods have therefore recently had a better chance. Chest clinics have increased in numbers and efficiency, and most places in the country are now at least fairly well served in this respect: before the war the service in many areas was meagre and of poor quality. Hospital beds have increased in number and adequacy in most regions. In both clinics and hospitals there are more medical staff, with better qualifications, and more nurses and other professional assistants: more surgeons have closed more cavities. In fact the resources of treatment are now well diffused, and for the first time begin to approach the standard required to make an impression on national mortality-rates.

The rapid acceleration of the rate of decline in the last two years must therefore be due to chemotherapy, supplemented by the other resources of treatment.

Chemotherapy has, however, had another effect—one seen at the introduction of each new advance in treatment. The advance is always declared likely to diminish the need for beds, and to shorten the stay of patients in hospital; this optimism always proves premature. It is true that, for some patients, the total period of treatment has been less than if they had been ill some decades ago; but the new methods have drawn into the treatable group patients for whom little could previously have been done, and now a high proportion of patients are likely to receive specific treatment—treatment which has a reasonable chance of producing substantial improvement or even complete recovery. Thus, as always, there seems to be an increasing demand on treatment facilities. Now that treatment is able to help such a high proportion of the tuberculous, and that its influence is reflected in the mortality-rates, we may really hope that the day is coming when the demand will begin to decline; but that time is not yet. The trend of treatment may follow two lines. One group of patients will probably have minimal disease, discovered early, treated promptly with a large measure of success. The other group will contain a diminishing number of patients with untreatable disease requiring an increasing length of institutional treatment; and finally there will become a small number kept under treatment for life. More and more will be treated less and less, and less and less be treated more and more.

A.P. or extrapleural A.P...	39	41	29	33
Thoracoplasty	5	25	10	35
Resection of lung ..	—	5	3	11
Chemotherapy	40	67	62	82

Figures against treatment are percentages of the total of patients: these do not add up to 100, because a patient may have combined treatment.

In selected groups treatment was able to improve the chance of survival even before the advent of modern chemotherapy. At Clare Hall Hospital the more effective use of collapse-therapy improved the general survivor-rate of patients during the early war years, 1939–43 (Simmonds and Martin 1948).

The emphasis on various forms of active treatment, however, has changed during the last ten years. The table shows the frequency with which we at Clare Hall have been using various methods in the last two years. We have noted a great increase in the proportion of patients admitted with negative sputum: in 1950, only 28·5% of both the men and women admitted were sputum-negative on admission, but in 1951 this rose to 44% of men and 45% of women (fig. 3). More patients, then, have been rendered sputum-negative by treatment before admission—partly by rest at home, but especially with the aid of chemotherapy. Such sputum-conversion might well be transient but for further treatment by collapse or active measures; and the table, in fact, confirms that disease in the sputum-negative may be just as extensive and need other treatment almost as often as disease in the sputum-positive.

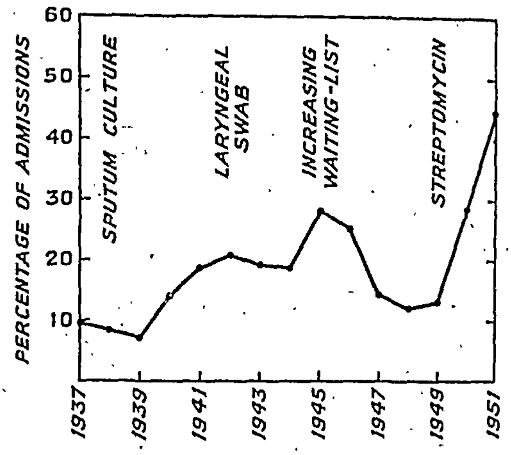

Fig. 3—Percentage of patients sputum-negative on admission to Clare Hall, 1937-51.

Fig. 4 shows how the use of various treatments (or the fashion) has changed in the last ten years. Pneumothorax, once the only active method of treatment available, is now almost abandoned in some quarters. At Clare Hall, though, we still use it moderately; this is often because the lesser disease is controlled by pneumothorax while a more severe lesion on the other side is treated by different means. Nor would this degree of popularity survive if chemotherapy had not rendered artificial pneumothorax safer in its limited field than formerly.

Pneumoperitoneum remains a very useful weapon, mostly employed for a limited purpose and restricted period. Its old associate, phrenic nerve crush, is now rarely done, for pneumoperitoneum plus chemotherapy is a better combination. Modern trends have given chemotherapy a large part in treatment, but we do not expect effective control of pulmonary tuberculosis by this means alone. Mechanical methods of cavity closure, or excision of tuberculous foci remain the chief treatment of destructive tuberculosis. Even apparent success by chemotherapy alone is usually temporary. The combination of rest, chemotherapy, and pneumoperitoneum is very valuable for the less extensive type of lesion. Most patients with post-primary pulmonary tuberculosis requiring treatment need chemotherapy at *some* stage, but it must be wisely integrated with rest and active methods.

Surgical Trends

(R. L.)

The present trend in the surgery of tuberculosis is towards excision rather than collapse of the affected part

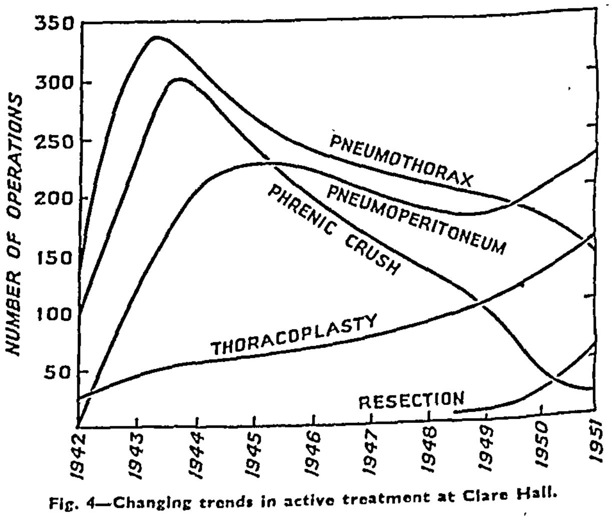

Fig. 4—Changing trends in active treatment at Clare Hall.

of the lung: indeed, in some centres excision has almost replaced surgical collapse.

SURGICAL COLLAPSE

I have begun an investigation into the results of thoracoplasties performed at Clare Hall for pulmonary tuberculosis—that is, excluding those done to close empyemata and pleural spaces after pneumonectomies. In the six years 1944–50 there have been 580 patients treated in this way; 12 died within six months after the operation—a mortality-rate of 2·1%; and since the operation is usually done in two or more stages this means a mortality-rate of less than 1% per operation. The cases were of all types, some good and some bad, and in some patients there had been little hope of sputum-conversion by thoracoplasty. Nevertheless, 72% of the 580 were sputum-negative to the most searching tests for tubercle bacilli during the two months before their discharge. If the worst cases are excluded, the percentage of negatives rises to over 80. These figures are on the whole satisfactory and show that thoracoplasty has still a very definite place in the treatment of pulmonary tuberculosis.

In modern thoracoplasty, usually done in two stages, the upper 5–7 ribs are removed. Not all types of disease are suitable, and we now have a much better idea which will not respond to collapse. Unsuitable cases are in the main those with associated severe and persistent bronchial disease, and those with large solid foci, gross cavitation, or disease of lower lobes.

Various extrapleural and extrafascial operations without extensive rib resection may be grouped with thoracoplasties. Until about eighteen months ago we did some 20–30 extrapleural pneumothorax operations yearly at Clare Hall, usually for patients needing bilateral surgery. After the extrapleural pneumothorax operation, the space was maintained by refills of air at high pressures; but a few years ago surgeons began filling the space with plastic substances instead of air refills. ‘Lucite’ balls were, and still are, used, but these hard round spheres offer pressure points. Morriston Davies et al. (1951) use a ‘Polythene’ pack filled with strips of polythene. This seemed a more congenial substance and I was considering using it when I was sent, for trial, a ‘Polystan’ sponge made of polyethylene. This has proved most satisfactory. It is readily sterilised by boiling, and we have seen few complications from its use. I tried it first in October, 1951, and since then we have used it in some 50 operations. The method is to bare the upper five or six ribs, and reflect down most of their periosteum and intercostal muscles, still adherent to the lung. A good solid roof is thus formed which separates the lung from the filling material. This type of operation is popular with the patients, since it is a single event and there is no deformity. We use it in patients with apical disease, in whom the ribs can be stripped reasonably easily. Cases with large solid foci and constrictive bronchial disease are not suitable. We do not know yet whether the sponges will need to be removed later, but I earnestly hope that they will become part of the patient and remain happily in situ for the remainder of his life.

RESECTION

We now use pneumonectomy, lobectomy, segmental resection, and wedge excision of the lung in the treatment of pulmonary tuberculosis; and fortunately many of the patients who are unsuited for collapse can have the affected part of the lung removed. The indications are:

1. *A destroyed lung where the other lung is healthy, or has a small amount of disease which is now stabilised.*—About a third of the resections performed at Clare Hall Hospital have been done for this type of lesion, with dramatic results. Patients who have been ill, toxic, and bedridden have been restored almost to normal health: they are able to do sedentary work, and, except for slight breathlessness on exertion, lead a normal life.

2. *Permanent bronchial stricture with tuberculous disease beyond.*—Collapse therapy has little to offer these patients and the diseased area, including the stenosed bronchus, should be removed.

3. *Large solid foci or tuberculomata.*—Some of these lesions run a comparatively benign course, others erupt and cause spread. It is difficult to tell which will cause trouble later, but on the whole it seems wise to remove the larger foci. These lesions can readily be removed by segmental resection or wedge excision of the affected part.

4. *Large or tension-type cavities.*—Where these are present in the upper lobe, lobectomy can be done. At times, at thoracotomy, disease is found in the apex of the lower lobe, which did not show on X-ray examination. This can be removed by segmental resection or wedge excision; if it is left the over-expansion which follows lobectomy may cause breakdown in such areas.

5. *Failed collapse therapy.*—If cavitation persists under a pneumothorax, or following a thoracoplasty, lobectomy should be performed.

6. *Lower lobe cavitation.*—Lobectomy should be done when a lower-lobe cavity fails to respond to a pneumothorax, or to phrenic crush and pneumoperitoneum. It is important to know something of the natural history of the disease, for a cavitated primary focus may be followed by apical deposits later. It is best to avoid extensive resections if further pulmonary disease is expected.

7. *Empyema associated with gross lung disease.*—A pleuropneumonectomy is performed.

The results of resection in the right type of case are excellent; sputum conversion is over 90%. At Clare Hall the number of deaths after 132 resections for pulmonary tuberculosis has been 6 (4·5%) in the six months following operation.

Artificial Pneumothorax and Pneumoperitoneum

(N. M.)

ARTIFICIAL PNEUMOTHORAX

In the past few years artificial pneumothorax has suffered a considerable decline in popularity, and it is instructive to consider why this has befallen such an important and established method of treatment.

First, there has been an alteration in the type of case admitted. A large proportion of those now reaching us require major surgery. Patients with a lesion of limited extent, suitable for treatment with pneumothorax, now reach us comparatively seldom: they are being treated by the physician at the chest clinic. Pre-sanatorium selection, however, is not alone sufficient to account for the decline, which began rather earlier than our change in practice.

Artificial pneumothorax is associated with a good many complications (some of them severe and occasionally fatal) such as air embolism, spontaneous pneumothorax, empyema, and bronchopleural fistula. Such complications can often be avoided—either by postponing induction or by re-expanding the lung if the pneumothorax is unsatisfactory, but even so we are not using pneumothorax more—even in the comparatively safe type of case—but a good deal less. Clearly, the risks are not to be ignored. While we may not get empyemata nowadays, we still get fluid, even with the most wary precautions; and atelectasis—even massive atelectasis—is not uncommon. Chemotherapy has made A.P. safer, but has not made it more widely used. Rather it has increased the popularity of *other* methods—particularly resection, but also the more permanent forms of collapse therapy, such as thoracoplasty and plombage, for which the patient can now be more adequately prepared.

The practice of collapsing the lung by pneumothorax only began to reach *large*-scale proportions in this country during the last ten or twelve years. Hence it is only in the last few years that we have been able to see what happens when the refills are stopped. We are thus beginning to develop a more proper appreciation of the late or ultimate results of pneumothorax therapy, and in some respects this has proved disturbing.

Thus a pneumothorax may force you to give it up because refilling it becomes increasingly difficult or even hazardous. Moreover, the best time to stop refills is still the subject of conjecture. Statistics suggest that it is best to terminate a pneumothorax after about three years, but not only may the doctors disagree about the time for its termination, but the patient may prove resistant to the suggestion, preferring to continue with refills more or less indefinitely: "I feel safer with it, doctor."

And even when it has been agreed that the best moment has been reached, the lung may not oblige by re-expanding in the desired way. Because of pleural thickening or old-standing bronchial stenosis, re-expansion may, in fact, be impossible; or possibly only at the cost of gross mediastinal distortion. The doctor is then faced with the problem of maintaining refills indefinitely or submitting the patient to some form of major surgery—either thoracoplasty, plombage, or decortication—which at this stage in the life-history of his illness he may not altogether welcome.

There is also the continual fear that the hazard of re-expansion may not be successfully overcome. We know that the overstretching of lung tissue which contains diseased foci does not favour healing—quite the reverse. There is also the risk of the unexpandable lobe, which is usually more dangerous than the unexpandable lung. Pneumothorax is usually done for upper-lobe disease, and sometimes this results in atelectasis of either the whole or part of the upper lobe which then rests like a little knob on the lobe below. If this collapse of the upper lobe is permanent, as it quite often is, when the pneumothorax is given up the lower lobe over-expands; and if there are foci—particularly in the *apex* of the lower lobe—breakdown with cavitation is quite possible. Even in the absence of relapse there may be considerable impairment of pulmonary function, due to thickened pleura, bronchial stenosis, pulmonary fibrosis, and compensatory emphysema.

All this adds up to uncertainty—which is the bugbear of pneumothorax therapy from the start, if not before. Other methods are not free from uncertainty, but with them it usually does not go on for such a long time. With pneumothorax the risk of major disaster is present for rather too long. In the early stages there is tuberculous pleural infection, and atelectasis. The pleura is extremely susceptible to the tubercle bacillus; it is also quite a large membrane (about $2^{2}/_{3}$ sq. ft. if laid out flat) and every square inch of it may become tuberculously infected. Pneumothorax, too, is a *temporary* form of collapse and some day the hazard of re-expansion has to be faced; this is always a period of uncertainty.

In recent years we have repeatedly tried to reduce its uncertainty. We kept the patient in bed for a longer time, to reduce his toxicity to a minimum; sometimes we added a phrenic crush to give relaxation without the risks attendant upon separating the pleural layers. Then we did pneumoperitoneum as a "cooler." Later on we made sure that the patient, if at all toxic, had an adequate course of chemotherapy beforehand. Next we started bronchoscoping the patient before induction to make sure he was free from tuberculous endobronchitis. Each of these steps had the effect of diminishing the field in which we felt pneumothorax could be safely applied, until now we are getting to the point where, in order to avoid all avoidable complications, we are quite likely not to do the pneumothorax at all. We have stopped doing it in the toxic patient; and we have stopped doing it in the emphysematous patient, to reduce the risks of "spontaneous" and air embolism. Or, having rested the patient and given him a pneumoperitoneum, perhaps with a phrenic crush as well, we sometimes find it scarcely necessary to proceed to pneumothorax. Or having given a thoroughly good course of chemotherapy, we again find A.P. unnecessary, or decide something else would be better. Or having bronchoscoped the patient and *found* tuberculous endobronchitis we are put off doing pneumothorax, whatever else we may or may not do. Unhappy experience has led us to regard some other things as contra-indications—for example, the presence of a large tension cavity, or a segmental lesion, or a thick-walled cavity which has resulted from the liquefaction of a solid focus. We hesitate to do a pneumothorax if there is too *much* caseation (tomograms incidentally have helped to reveal the size and extent of caseous foci) and, of course, we hesitate if there is too *little* disease. We won't do pneumothorax if the disease is too *new* or if the lesion is too *old* and fibrotic.

The positive indications for pneumothorax therapy, then, have been progressively disintegrating, and it has become increasingly difficult to pick out a patient and say with certainty: "This patient really must have an A.P. because it affords him the best chance of permanent recovery."

I have said that alternative methods appear to offer a better long-term result. But these methods, if they are to displace A.P. therapy, must not only be successful—they must also be available. We are fortunate here in having two full-time thoracic surgeons; but in the chest clinic even the most resection-minded of physicians could only get a limited number of his cases treated in this way and would be forced, willy-nilly, to use pneumothorax in a good many cases. Even here we still do more A.P.s than resections though the curve of the one is rising and of the other falling. There are centres, however, where pneumothorax has been shown the door: in Holland, I believe, it is now scarcely done at all, and even in this country we have resection-minded Liverpool and Sully.

We are, in fact, seeing a period of rapid change in the treatment of tuberculosis. Ten short years ago A.P. and thoracoplasty were the accepted standard forms of treatment with extrapleural causing a flurry in the dovecot. Chemotherapy was not used, resection was heresy, and pneumoperitoneum had scarcely begun. Now we are not only questioning the value of pneumothorax therapy, but thinking of replacing even the trusty thoracoplasty with an operation which will be less physically damaging. Already it is being suggested that chemotherapy and modified resection (segmental or wedge resection) will prove the most reliable long-term measures—thus displacing collapse therapy from its established position. In these circumstances it would be unwise to attempt a final pronouncement on any form of therapy. Pneumothorax, properly applied and properly managed can, of course, still give good results, and many patients have benefited from it in the past; but this does *not* necessarily prove that it is the *best* form of treatment. There is more than one way of treating tuberculosis successfully, and the ultimate test will be the long-term results. Until these become available there will be room, and to spare, for divergence of opinion.

PNEUMOPERITONEUM

Pneumoperitoneum is in a different position from pneumothorax. After a spell of what was probably over-application P.P. has settled down to a steady level which it appears to be maintaining. This position, *too*, is being held in spite of two factors which might have been thought to have affected it adversely.

First, chemotherapy has reduced its use as a "cooler" for the toxic case, and might have replaced it entirely. But in many of these cases we *still* find it *useful* to supplement chemotherapy, after a short interval, with pneumoperitoneum. This particular attribute of pneumoperitoneum—its ability to supplement other forms of treatment without interfering with them or *displacing* them—is one of its strong points. The good results of chemotherapy, we feel, can be improved and to some extent consolidated, by establishment of a pneumoperitoneum.

Secondly, its one-time trusty companion, phrenic paralysis, is now out of favour. We used to think that the results of P.P. were often enhanced by a phrenic crush on the appropriate side, but gradually have come to criticise this combined therapy. When the diaphragm is paralysed the position is not so readily reversible as with P.P. alone: the diaphragm needs time to recover its function. Sometimes, indeed, it does not recover, or recovers only partially; and almost always it remains high with diminished power of contraction. Hence respiratory function is limited, and this may prove a grave handicap when bilateral active treatment is needed later. Moreover, the surgeons dislike it because it may increase the chance of massive collapse at the time of thoracoplasty. For these reasons phrenic crush has gone quite out of favour, though the old combination of "P.P. and phrenic," is still useful to make good the space deficiency after removal of a lobe.

We find P.P. alone of particular value, in association with chemotherapy, for the treatment of a specific and readily recognisable type of case—pulmonary disease of hæmatogenous origin. Here the foci are usually in the upper zones of both lungs, and distributed symmetrically. Cavities are usually apical and thin-walled, and produce little sputum; and perhaps because of this, tuberculous endobronchitis is relatively uncommon. There is a strong tendency to fibrosis, the upper lobes shrinking and drawing up the hila, and the lower zones show compensatory emphysema. Such cases often respond well to chemotherapy; and a P.P., by raising the diaphragm, relieves the emphysema in the lower zones to some extent and encourages the apical lesions to contract further. The results are in the main so satisfactory that with many patients one is strongly tempted to leave well alone—particularly as the alternative is often bilateral pneumothorax or bilateral surgery. But I would emphasise that the pneumoperitoneum will probably have to be kept up more or less indefinitely, for there is a distinct risk of relapse when the diaphragm is allowed to descend.

On the whole pneumoperitoneum is perhaps most useful as a temporary procedure, used and recognised as such, in preparation for some more major and permanent form of surgical treatment. It has retained our confidence because we know more or less what to expect from it—not too much, but a useful contribution, nevertheless, towards the patient's recovery. Moreover, it is reasonably safe. Pneumothorax aims rather higher but is apt to fall down somewhat heavily; P.P. seldom o'erleaps itself.

CONCLUSION

The whole field of therapy is undergoing a rapid change, and our changing attitude to A.P. and P.P. is only one aspect of it. Chemotherapy has been mainly responsible. Besides consolidating the ground already held, it has driven a whole new salient—indeed a series of salients—into territory previously under the control of the tubercle bacillus. In this extended ground there is more room for us to manœuvre—to develop new ideas, new techniques, new lines of attack. We have moved forward: already the position is vastly changed. There is, of course, no need to cast away all the old ideas, all the old techniques; but it behoves us to re-examine them, to compare them as fairly as we can with the new—and where necessary be prepared to discard them, even if it hurts.

SENIOR REGISTRAR, SKIN DEPARTMENT, LONDON HOSPITAL

IN furunculosis and sycosis barbæ staphylococci are commonly carried from a lesion to infect the skin elsewhere. From the earliest stage of a boil until healing is complete, virulent staphylococci can readily be isolated from the overlying and surrounding skin; and, unless suitable precautions are taken, they are conveyed thence, by fingers or handkerchief, to other parts of the body—including sites where they are liable to persist, such as the nose, eyes, and external auditory meatus. Recurrent infection in the axilla—a warm, moist, dark, and hairy area, with apocrine glands—is readily understandable.

By eliminating the micro-organisms from the surface of the body, it should be possible to prevent this kind of spread and so bring the infection to an end. In a series of cases of sycosis barbæ, Burrows, Russell, and May (1945) used penicillin cream for this purpose, applying it both to the lesions and to the nose. The clinical response was usually good whenever the strain was sensitive to penicillin. Similar results were reported by Hobbs, Carruthers, and Gough (1947), who found that the strains from lesion and nose corresponded serologically in all the 17 cases tested. Penicillin cream usually cleared sensitive strains from the nares, though relapse might follow reinfection. Some cases showed evidence of sensitisation to penicillin, as would now be expected.

Dolman (1935) was the first to observe that in chronic furunculosis the anterior nares are often infected with *Staphylococcus pyogenes*. One of us (Valentine 1936) found that the production of hæmolytic and leucocidal toxins by strains derived from lesion and nose was usually comparable. Thereafter other workers, whose results are summarised by Miles et al. (1944), demonstrated a high rate of carriage in the general population, the figure varying from 22 to 47% in different investigations. Since the latent carriers greatly outnumber the cases of active infection, the significance of nasal carriage in the latter may have escaped notice, the more so because, with staphylococci, there is no recognised test for virulence as opposed to pathogenicity. It is reasonable, however, to assume that the strain isolated from a lesion is unusually virulent, at least in the particular patient concerned, and that the presence of the same strain in the nose may help to produce further lesions.

Miles et al. (1944), who obtained the highest figure (47%) in their sample of the population, also showed that in some people the swabs were constantly positive and in others negative, but that in most cases the results were inconstant, being sometimes positive and sometimes negative. Ability to get rid of pathogenic staphylococci from the nose varied, in fact, in different people. In our own investigation it has not been possible to show that the majority of the patients were constant carriers, firstly because the nasal infection, if constant, might have been maintained from lesions, and secondly because we were dealing with outpatients expecting active treatment. We were forced to assume that most of those with heavy nasal infection were constant carriers.

Rountree and Barbour (1951) investigated nasal infection in student nurses before and after entering the wards for training. Using bacteriophage typing of the strains isolated they found that, although the percentage of carriers rose after the nurses entered the wards, the permanent carriers usually kept their original strains, and that from 90% of positive swabs only one strain was isolated. We could therefore hope that, if the original strain were eliminated from the nose of a patient, permanent infection with a less virulent strain might follow.

PLAN OF INVESTIGATION AND TREATMENT

(1) At the first interview the usual history was taken, with special reference to previous lesions in the nose, eyes, or ears. It was then carefully explained to the patient that infection was due to minute living organisms in the discharge, which were readily carried to other parts of the body by the fingers and often settled in the nose or elsewhere. This explanation took little time and almost always gained the patient's coöperation.

(2) Swabs were then taken from the lesion and the probable sites of carriage; the nose and eyes should never be omitted. The number of colonies of pathogenic staphylococcus was roughly estimated, and the strains were kept for reference after tests for sensitivity.

(3) 1% cetrimide (' Cetavlon ') was prescribed for cleaning the skin round the lesions at each dressing, and 3% terramycin ointment was given to be applied after the cetrimide; lesions must receive treatment until completely healed. The ointment must also be used twice daily in the anterior nares (and, if necessary, at night on the margins of the eyelids) for four weeks without fail. After a rest of three or four weeks further cultures were taken.

(4) Patients were warned that sensitisation might develop, in which case treatment must stop at once. Some of those with a history of sensitisation to other agents were told to test an uninfected area exposed to light, such as the forehead, for two days before treating any region of infection.

(5) After shaving, patients with sycosis barbæ usually wash off the remaining lather. Water, with its low osmotic pressure, is somewhat irritating after the slight trauma of shaving, and in any case may not be free from infection. Such patients were therefore told to wipe off the lather and then to apply cetrimide and, finally, the ointment.

FINDINGS BEFORE TREATMENT

Table I shows that 53 cases of recurring furunculosis were seen. Only 16 of these were in women, of whom 8 were nurses. The nurses were all infected with penicillinase-producing staphylococci. It will be seen that there was a heavy infection of the nares in 64% of the cases and some degree of infection in 80%. These figures may be compared with a maximum of 47% in the general population (Miles et al. 1944) and with the results obtained from single swabbings of student nurses at the London Hospital (62% infected and 44% heavily infected). Since no previous record of the kind could be found in the literature, it was thought desirable that the strains from lesion and nose should be compared by bacteriophage typing. Dr. R. E. O. Williams, on consultation, agreed to do this, and we are deeply indebted to him and his colleagues for the typing of no less than 100 strains, including some isolated after treatment and some from other sites of carriage than the nose. The strains from lesion and nose were typed in 25 cases and were the same in 19, probably the same in 5, and different in only 1 case, in which the patient had had boils, mainly on the buttocks, for five years, and the strain from a boil on his wrist corresponded to one isolated from his anal region. For the criteria by which the results of phage-typing are judged, see Williams and Rippon (1952).

TABLE I—BACTERIOLOGICAL FINDINGS BEFORE TREATMENT

—	Boils and styes	Sycosis barbæ
Total	53	36
Nasal carriage :		
Heavy	34 (*64%*)	27 (*75%*)
Light	9	6
Negative	10	3
Penicillin-sensitive ..	38 (*72%*)	15 (*42%*)

The rate of nasal carriage appears to be even higher in sycosis than in furunculosis. In view of the work of Hobbs et al. (1947) the strains from lesions and nose were compared for pigment production and sensitivity to penicillin and terramycin, and in all cases they appeared to be similar; but they were not typed. The relatively small number of strains sensitive to penicillin suggests that our patients are in the main those who have failed to respond to penicillin.

In 1 case of boils and 2 of sycosis the eyes were more heavily infected than the nose, and it therefore seems advisable that the eyes should be included in the routine preliminary tests.

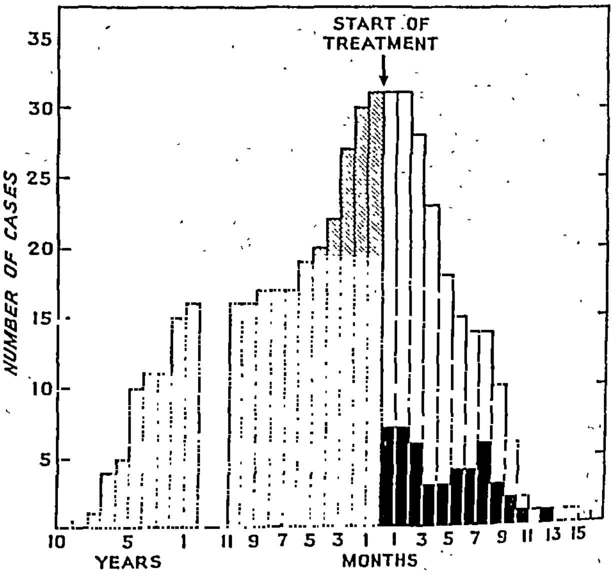

Fig. 1—Length of past history and follow-up of cases of furunculosis.

CLINICAL RESULTS

In 31 cases of boils and 24 of sycosis the course of treatment was completed and the follow-up period was long enough to give an indication of the immediate results.

Figs. 1 and 2 are designed to give a picture in bulk of the length of past history and of the follow-up, but do not portray the experiences of individual patients. Thus, in the series with boils (fig. 1) the history extended to one or more years in 16 cases and to months only in the rest. In the follow-up period the unit of area corresponds to one month per patient and is heavily shaded if lesions persisted but clear if they did not; thus in the first month of treatment fresh lesions appeared in 7 cases only. This is a form of presentation which is better suited to a continuous process, such as sycosis barbæ (fig. 2), than to furunculosis; in the latter, especially, a longer follow-up period is clearly necessary.

Tables II and III refer to furunculosis and sycosis respectively, and show the clinical results in relation to the bacteriological findings in the nose before and after treatment. The numbers in parentheses refer to cases requiring discussion.

Table II shows that in 23 cases the nares were heavily infected. After treatment nasal cultures were negative in 10 cases, with 1 case (case 40) of persisting active

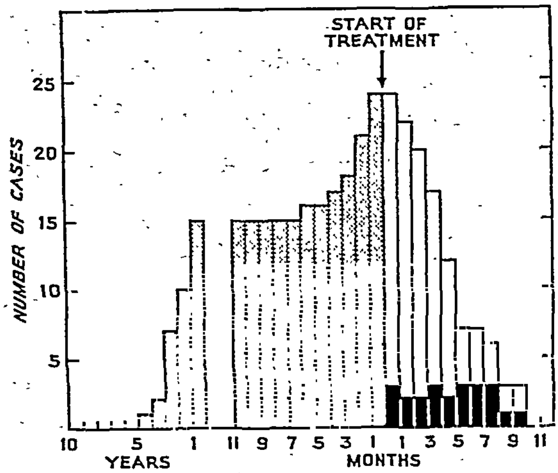

Fig. 2—Length of past history and follow-up of cases of sycosis barbæ.

infection; this man's boils were in the pelvic region and axillæ, where complete eradication of infection is difficult. Of the 7 patients in whom a new strain was isolated from the nose 4 have done well, 1 has had a minor recurrence in the nose, and in case 47 the original strain has persisted in the axillæ, although the nasal strain has changed. (This man is a poor attender and correspondent, and has not reported on his condition since told to shave his armpits three months ago.) The other case of minor recurrence (case 8) is of special interest; the patient gives eight years' history and has never attended with an active lesion, but the nasal strain has changed after treatment and is now moderately resistant to terramycin; it is not known which strain was present in a relapse after ten months' freedom. In the 6 patients with persisting nasal infection, 3 with the same type and 3 with probably the same, the clinical results have been less satisfactory, notably in case 24, a young lady who has not carried out the treatment, owing to irritation in the nose after using the ointment. 4 other patients in this group have shown a tendency to relapse when treatment of the nose stops, and cannot be regarded as cured; possibly in some there is a chronic sinusitis from which the nostrils are reinfected.

The remaining cases present a different problem in that the usual site of carriage was innocent. Case 45 during a recent relapse showed a heavy infection of the eye, which had not been tested earlier, and case 92, as has been described, showed infection in the anal region. In the others it is presumed that the skin around old lesions has retained the infection; in case 30, for instance, the boils are usually confined to the right arm. Case 53 is of interest in that the lesions, due to an *aureus* strain producing penicillinase, have recurred after an interval of seven months, during which the nose has been "occupied" by a sensitive *Staph. albus.*

TABLE II—FURUNCULOSIS: RESULTS OF TREATMENT IN RELATION TO NASAL INFECTION

Nasal swabs		Clinical results		
Before	After	Good	Recurred	Failed
Positive ..	Negative	9	..	1 (40)
	New strain	4	2 (8)	1 (47)
	Persisting	3	2	1 (24)
Scanty ..	Negative	1	..	..
Negative ..	Negative	3 (92)	2 (30, 45)	1 (4)
	New strain	..	1 (53)	..

TABLE III—SYCOSIS BARBÆ: RESULTS OF TREATMENT IN RELATION TO NASAL INFECTION

Nasal swabs		Clinical results		
Before	After	Good	Recurred	Failed
Positive ..	Negative	11	..	..
	New strain	3	1 (15)	1
	Scanty	2	..	1 (39)
	Persisting	..	..	1
Scanty ..	Negative	3	..	..
	Scanty	1	..	..

"Persisting," many colonies of *Staph. pyogenes.* "New strain," *Staph. pyogenes* of different phage-type. "Scanty," few colonies of *Staph. pyogenes.* Numerals in parentheses refer to individual cases.

We would again emphasise the importance, in sycosis barbæ, of discovering and treating sites of carriage, such as the nose and eyes, although one cannot say how often the nasal infection was merely maintained by transfer from the face. Our cases (table III) included 11 of deep folliculitis or sycosis vulgaris and 13 of superficial folliculitis; 7 cases had a decidedly seborrhœic background. The response to treatment was impressive and rapid, being at least comparable to that obtained by Solomons (1951) with 3% aureomycin ointment; 2 cases of severe lupoid sycosis have shown an immediate improvement but required a prolongation of the treatment to eight weeks in all. Of the cases shown as failed, 2 were in fact much improved, but the prognosis is far from satisfactory; the 4 patients with poor results were all psychologically somewhat abnormal, case 39 actually attending a psychiatric clinic. Case 15 is of interest in that relapse occurred four months after treatment began, and was associated with a resistant strain; most unfortunately the original organism was lost without being typed, but it was noted as producing penicillinase, whereas the later strain is sensitive to penicillin.

DRUG RESISTANCE

In addition to the simple agar-diffusion test for sensitivity to terramycin, samples from broth cultures have been streaked on agar plates containing the drug in different concentrations, in such a manner as to yield areas of single colonies on the control plate containing no terramycin. With two exceptions, all the strains tested in this manner showed delayed growth at a concentration of 0·4 µg. per ml. and complete inhibition of individual colonies at 1·6 µg. per ml. Latterly it has seemed enough to use plates containing 2 µg. per ml., which inhibited growth of the thinly spread inoculum from 115 strains, including 21 isolated after treatment. Two strains proved resistant to 25 µg. per ml.; they were isolated after treatment from cases 8 and 15, are probably both of them changelings, and may well have been resistant from the first. Since the development of resistance seems to be rare, we have been encouraged latterly to repeat the treatment where necessary or to treat for longer periods in old cases of sycosis associated with scarring. Clearly, however, casual intermittent treatment over long periods is to be condemned.

SKIN SENSITISATION

The development of sensitisation of the skin often follows the use of penicillin cream. Solomons (1951) reports a similar condition in 2 patients after the use of aureomycin ointment. In 1 of our cases of sycosis, sensitisation to terramycin ointment developed after eight days' treatment, by which time, most fortunately, the staphylococcal infection had been eradicated from both face and nose; the ultimate result was good. In another patient, a woman with thyroid disease with a history of sensitisation to thiouracil, terramycin ointment was given for treatment of facial pustules by a bacteriologist (F. C. O. V.) without dermatological advice, and led to an immediate and severe exacerbation of the condition. Though sensitisation seems to be uncommon, the testing of the preparation on uninfected skin seems to be a reasonable precaution when there is a history of reaction to other drugs.

DISCUSSION

In this series of cases of superficial staphylococcal infection, the nasal carriage of pathogenic cocci was commoner than in the general population. In furunculosis the strains from lesions and nose were nearly always of the same type, as has been shown by Hobbs et al. (1947) in sycosis barbæ. Since the possibility of constant reinfection of the nose from the lesions could not be excluded, there is no proof that these patients were permanent carriers like those described by Miles et al. (1944) and Rountree and Barbour (1951). But the presence of a considerable minority of cases in which pathogens were few or absent in the nose suggests that in the majority the nasal infestation was lasting and helped to maintain infection. Where the nose is innocent, other sites—e.g., eyes, ears, and axillæ—should be considered before concluding that infection is only being spread from one lesion to another.

The treatment which we have used has the disadvantage of being somewhat laborious, particularly for the patient, a fact which may well explain some of our failures. But we have been struck by the manner in which nearly all the patients responded when the problem was described to them. A simple explanation of the spread of staphylococcal infection is therefore essential in obtaining the patient's coöperation. Even so, it may sometimes be found that the nose is being treated while even more important areas around recent lesions are neglected. For the doctor's guidance the results of swabs taken from lesion, nose, and eyes are very desirable, and whenever possible these should be taken in the laboratory to avoid delay in culture. The need for further cultures will depend on the clinical results.

At first we intended to avoid using antibiotics suitable for systemic administration, for fear of breeding resistance in the staphylococci or hypersensitivity in the patient, and thus preventing the use of the drug in a future emergency. A few of the earlier patients were given 'Quinolor' ointment, to use in the nose for an indefinite period, with some degree of success; but the nasal infection persisted although its dissemination was largely prevented. As soon as it was found that terramycin ointment might sometimes eradicate the nasal infection its further trial seemed to be justified, provided that the course of treatment was limited in time and thoroughly carried out. Even so two resistant strains have been isolated after treatment—resistant also to aureomycin but not to chloramphenicol. These appear to be new strains, perhaps possessing intrinsic resistance; but the widespread use of terramycin might well encourage the dissemination of such strains, as has happened with penicillin (Barber and Rozwadowska-Dowzenko 1948). It would obviously be preferable therefore to use drugs which are not suitable for systemic administration.

The figures shown in the tables strongly suggest that, when pathogenic cocci can be extirpated from a nose which is heavily infected, the clinical result will usually be good. When reinfection with a fresh strain takes place, the results are more equivocal; but detailed study of the cases shows that only three of the twelve new strains isolated were definitely incriminated in the formation of fresh lesions.

SUMMARY

In most cases of persistent furunculosis and sycosis barbæ the anterior nares contain the same strain of staphylococcus as is found in the lesions. Occasionally, instead of the nose, the eye or some other region is the "site of carriage" or reservoir from which infection continues to be distributed. Infection also persists in the neighbourhood of a lesion until it is completely healed.

The scheme of treatment described is based on a simple explanation to the patient that infection is spread to other parts of the body, from lesion or nose, by fingers or handkerchief. All lesions are treated until healed, and terramycin ointment has been applied to the site of carriage twice daily for four weeks.

The clinical results are good, provided infection is eradicated from the site of carriage. Reinfection of the site of carriage with a fresh strain does not usually lead to clinical relapse.

Although no strain acquired resistance to terramycin, two resistant strains were isolated after treatment.

Sensitisation of the skin to terramycin ointment appears to be uncommon.

We wish to thank Dr. W. J. O'Donovan for his permission to study and treat so many of the patients under his care. Our great debt to Dr. R. E. O. Williams and his staff at the Staphylococcal Reference Laboratory, Colindale, has already been acknowledged in the text. We also want to thank Prof. S. P. Bedson and Dr. H. B. May for their advice and interest. For the supply of 3% terramycin ointment our thanks are due to the Antibiotics Clinical Trials (non-tuberculous conditions) Committee of the Medical Research Council.

ADDENDUM

Since this paper was written, the appearance and dissemination of staphylococci resistant to many or all of the newer antibiotics has been described (Lowbury et al. 1952, Clarke et al. 1952). The danger is greater in the case of inpatients since during bedmaking the nurses inhale dust and become nasal carriers of the resistant organisms. Our cases have been outpatients and the drug has usually been applied to relatively intact skin rather than to sloughing wounds in which resistance is readily bred; resistant strains have only appeared after treatment has been unduly prolonged, against instructions. None the less the widespread use in local treatment of drugs capable of systemic administration is clearly undesirable and we are investigating the use of other agents.

COLLES FRACTURE OF THE RADIUS

A METHOD OF TREATMENT

DENNIS WALKER
M.B. Lond., F.R.C.S.

SENIOR REGISTRAR, ORTHOPÆDIC DEPARTMENT, WEST LONDON HOSPITAL

Colles fracture takes place about an inch from the carpal articular surface of the radius and presents a remarkably constant deformity, the small distal fragment being rotated so that the articular surface faces downwards and backwards, instead of downwards, or downwards and forwards. In addition there is usually some lateral rotation, carrying the carpus and hand to the radial side and rendering the head of the ulna more prominent. The proximal fragment is often driven into the distal one to a varying extent.

A recognised but insufficiently emphasised concomitant is the fragmentation of the dorsal and lateral aspects of the radial cortex at the *site of fracture*, which must occur to allow the classical deformity. This fact explains the common instability of this fracture after reduction, and the high incidence of recurrent displacement.

It appears to be tacitly accepted that, although the bones may unite in a position different from the normal anatomy, function may be, and commonly is, good. An investigation was therefore instituted to see to what extent this is true, and if a particular method of treatment produced satisfactory anatomical position of the bone and normal function.

MATERIAL

350 patients, treated by two methods, were selected at random from the records. All had uncomplicated Colles fractures with displacement. Of the number selected, 151 attended for interview and were examined personally. In all the fractures reduction and splintage had been effected within a few hours of injury, and all had united.

The average follow-up period since injury was 5 years, with a maximum of 7 years and a minimum of 2 years. The average age was $55^{1}/_{2}$ years.

PROCEDURE

Every patient was asked the following questions:

(1) Is your wrist as good as it was before your injury?

(2) If not, in what way does it now differ?

(3) Can you wring clothes normally?

(4) Can you turn a stiff door-handle?

(5) Can you carry weights in the affected hand without any trouble?

(6) Do you get pain?

Every wrist was next examined and classified under the following headings:

(1) Clinically indistinguishable from normal.

(2) Good—no obvious visible abnormality, but with a palpable bony deformity.

(3) Fair—a visible deformity of minor degree.

(4) Poor—a gross and obvious deformity.

RESULTS

The results in the 151 cases are shown in table I. The symptoms complained of by 73 patients were as follows: pain in 60 cases; weakness in 48 cases; inability to wring clothes normally in 32 cases; and difficulty in turning door-handles in 11 cases.

DISCUSSION

Table I shows that only 65 patients exhibited the normal wrist anatomy, and 74 showed visible deformity, classified as "fair" or "poor." Since all these fractures had been reduced, there was a very high rate of recurrent deformity of obvious degree. Furthermore, the symptomless patients were those who showed chiefly normal or good wrists, whereas the ones with symptoms were found chiefly in the fair and poor classes.

TABLE I—RESULTS IN 151 CASES OF COLLES FRACTURE

Result	Symptomless	With symptoms	Total
Normal	54	11	65
Good	9	3	12
Fair	11	38	49
Poor	4	21	25
Total	78	73	151

It seems reasonable to conclude that union in anatomical position is more likely to give a symptom-free wrist, and that, if the fracture unites in a position different from the normal, function is unlikely to be satisfactory.

As stated above, these patients had been treated by two methods:

Method A.—In the outpatient department the fracture was reduced under gas-and-oxygen anæsthesia (in a very few cases local anæsthesia was used), and a plaster slab encircling two-thirds of the wrist and forearm was applied from the metacarpal heads to the upper forearm. It was secured with a cotton bandage, which was adjusted later if it became loose. The wrist was held in the neutral position as regards rotation, flexion, and extension, and in slightly ulnar deviation. In all the cases X rays were used to confirm reduction. Splints were removed in the 5th or 6th week and, if union was present, active use was permitted.

Method B.—The patient was admitted, and reduction was effected under general anæsthesia. A posterior plaster slab was applied and secured with a cotton bandage. In all the cases X rays were used to confirm reduction. On the patient's return to bed the hand was kept elevated, and active exercises were started at once. When the swelling had subsided (usually after 4 or 5 days), and not until then, further radiographs were taken; and if, as happened in most cases, there was any recurrence of deformity, the bones were again manipulated into their correct position. After this, and also in cases showing no recurrence of displacement, a complete unpadded plaster cast was applied, from the metacarpal heads and proximal palmar crease to the upper forearm. The plaster was well moulded round the radial styloid and into the anterior concavity of the radius just above its lower end. The wrist was held in slight palmar flexion and moderate ulnar deviation, and in neutral rotation. The hand was elevated overnight to check reactionary swelling, and the patient was discharged next morning. The plaster was removed in the 6th week after injury and, if union was present, active use was permitted.

TABLE II—RESULTS ACCORDING TO METHOD OF TREATMENT

Method	No. of patients	Average age (yr.)	Result			
			Normal	Good	Fair	Poor
A	79	$55^{1}/_{2}$	19	7	37	15
B	72	$56^{1}/_{4}$	46	5	12	10

The results according to the method of treatment are shown in table II.

COMMENT

In method B insistence is placed on applying finally a skin-tight plaster cast to the limb after reduction (obtained by two or more manipulations if necessary) and after all swelling has subsided. The plaster is thus moulded to bones no longer masked by œdematous tissues. It seems clear that method B produces a substantially greater proportion of normal and good wrists than does method A.

CONCLUSION

The expectation of normal or good function after a Colles fracture has united in an abnormal position seems to be unjustified.

There is a strong tendency to recurrence of deformity after reduction, and the best hope of obtaining union in a normal position lies in applying a well-moulded plaster cast to the part after all swelling has subsided. Only in this way are the bones likely to be held in the correct relationship. This method often necessitates two (or even more) anæsthetics, but the result of this form of treatment appears to justify this.

SUMMARY

The anatomical position of wrists which have sustained a Colles fracture is correlated with symptoms.

It is suggested that union in anatomical position be aimed at in every case, since it gives the best chance of normal function.

A method of treatment embodying certain principles is described and its results are given.

I wish to thank Mr. J. C. R. Hindenach for his advice, and Dr. W. E. Evans for access to the case-records of the late Mr. George Stephen.

RECOGNITION OF FUNCTIONAL DISORDERS OF THE SMALL INTESTINE

A. MORTON GILL
M.D. Lond., F.R.C.P.

ELIZABETH DE C. FALLE*
M.B. Lond., M.R.C.P., D.C.H.

From the Gastric Clinic, West London Hospital

OF 1500 new patients attending the gastric clinic at the West London Hospital during a period of three years (1948–51), 8 had long-standing abdominal pain, obscure in origin and resistant to treatment, and on radiological examination were found to have an abnormality of the ileum.

Functional disorders of the colon have received attention in the past twenty-five years from Ryle (1928), Spriggs (1931), and Hardy (1945). But similar disorders of the small gut have had scant notice, although many agents (psychological, hormonal, reflex, chemical, physical, vascular, bacteriological, allergic) can affect intestinal movement and secretion. The importance of recognising such a condition was brought home to us by the following case:

Case 1.—Miss A, aged 34, a clerk in a responsible post, had for five years suffered from intermittent attacks of diarrhœa with aching lower abdominal pain radiating to the left sacro-iliac joint and down the front of both thighs, indifferent appetite, and a sense of fullness and belching after meals. She was subject to migraine and dysmenorrhœa, and in cold weather her extremities became blue and numb. She was of a shy and nervous disposition but well adjusted in spite of emotional immaturity. Her appendix had been removed in 1945. Apart from abdominal distension and an appendicectomy scar, nothing abnormal was found on physical examination, and early investigations (barium enema, sigmoidoscopy, bacteriology of stools, radiography of chest) were unhelpful. A barium meal, however, showed 6 inches of irregular narrowing in the distal ileum (fig. 1).

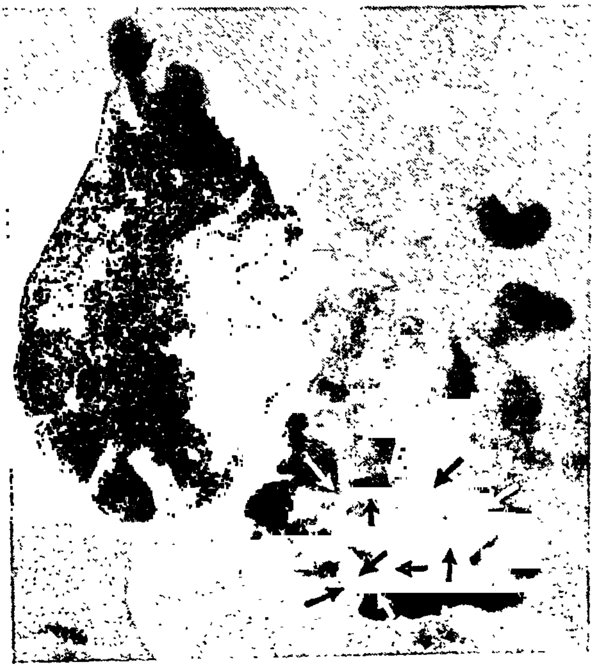

Fig. 1 (case 1)—Barium-meal radiograph showing 6 in. of irregular narrowing in distal ileum.

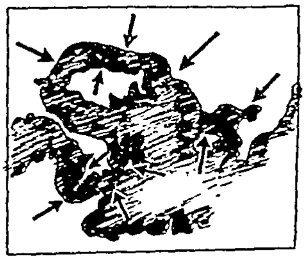

Tracing of spastic area in distal ileum.

Crohn's disease was diagnosed and laparotomy was done, but no abnormality whatsoever was found.

This case taught us that ileal spasm associated with abdominal symptoms could be sufficiently prolonged and severe as to mimic organic disease; and as a result other cases came to light. In these cases we had previously failed to recognise that the disorder lay in the small gut. Some of these patients had diarrhœa, others were constipated, none had normal defæcation.

CASES WITH DIARRHŒA

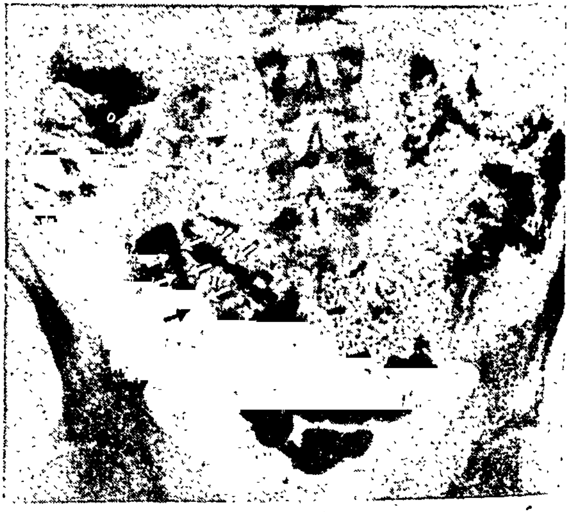

Fig. 2 (case 2)—Irritable loop in upper ileum with thickening of the mucosa.

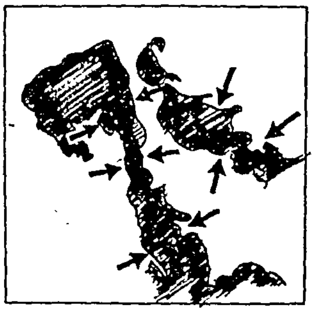

Tracing of irritable loop.

Case 2.—Miss B, a Civil Servant, aged 36, had had an appendicectomy at 16, jaundice at 30, and bacillary dysentery at 31 and again at 35. She had suffered from asthma and hay-fever since the age of 16. For two and a half years she had been troubled with intermittent lower abdominal and right sacro-iliac pain, radiating down the front of her right thigh, aggravated by walking and by defæcation, and relieved by sitting and while menstruating. These symptoms were accompanied by diarrhœa, with loose pale stools, anorexia, frequency and urgency of micturition, and a variable pyrexia. Two laparotomies, one in 1949 and the other in 1950, had failed to relieve her or to discover the cause of her symptoms. At the first laparotomy a broad-ligament fibromyoma was excised. At the second, endometrial cysts were removed from both ovaries.

When we saw her she was rather tense; she had hay-fever, a tender spastic sigmoid colon, and a ballooned cæcum. The erythrocyte-sedimentation rate (E.S.R.), a complete blood-count, examination of the urine, and radiography of stomach and duodenum, gall-bladder, and chest, and an intravenous pyelogram, were all normal. The Wassermann reaction of the blood and a gonococcal complement-fixation test were negative. Skin sensitivity tests were positive to mixed pollens and grasses and negative to intradermal histamine 1 : 10,000. Radiography of the small intestine, however, showed in the upper ileum an irritable tender loop

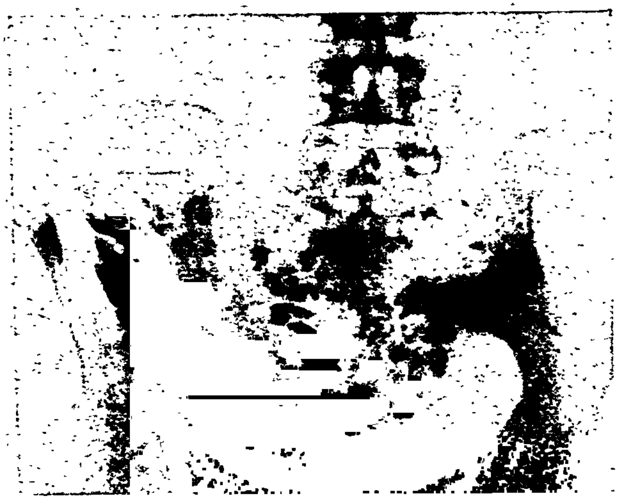

Fig. 3 (case 3)—Clumping and segmentation in small intestine (patient erect).

with evident thickening of the mucosa (fig. 2). The hay-fever responded to anti-histamines, but there was no improvement in the abdominal symptoms, nor were these affected by antispasmodics and sedatives.

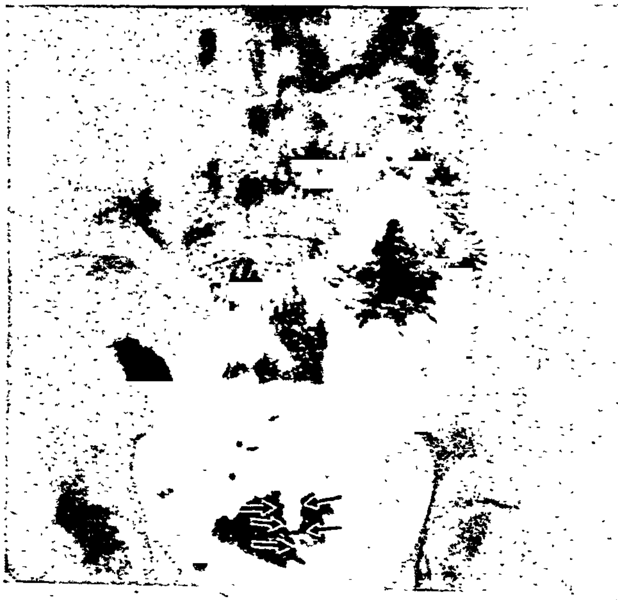
In endometriosis the intestines may become involved by the growth of endometrium on their walls or by incorporation of loops in a pelvic mass, the end-result being intestinal obstruction. This patient's intestines were not affected, and her symptoms remained unrelieved after removal of the diseased tissue.

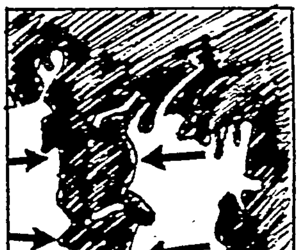
Case 3.—Mrs. C, divorced, aged 33, a packer in a factory, began at the age of 29 to have attacks, usually of sudden onset and lasting about eight hours, characterised by diffuse abdominal cramping pain, doubling her up and accompanied by malaise, sweating, nausea, vomiting, distension, and flatulence. Her stools, which were normally frequent and pale, became watery and more frequent. Apart from these bouts she had frequency of micturition, dysmenorrhœa, and attacks of urticaria, and her extremities became very cold in winter. She had never been pregnant. Appendicectomy in 1948 had failed to improve her health.

Seen by us in an attack her face was flushed, weals were visible on her chest and back, her abdomen was soft, distended, and diffusely tender, and her temperature was 99°F. Her personality was somewhat immature, her intelligence average. A barium meal showed small-gut hurry, clumping, and segmentation (fig. 3), but the fat-content of the stools was 26·3 g. per 100 ml., of which 16 g. was split, and fat-balance (Cooke et al. 1946) showed that 97% of ingested fat was absorbed. There was no response to folic acid. A complete blood-count, estimation of the plasma-protein level, a histamine test-meal, and bacteriological examination of the stools gave normal results. Skin sensitivity tests were positive to mixed inhalants, mixed grasses, pollens, and intradermal histamine 1 : 10,000. Histamine desensitisation, and anti-histamines, antispasmodics, and sedatives were all without effect.

A year later a further barium meal showed persistence of the abnormal pattern, and passage through the gut was so rapid that the head of the meal was at the splenic flexure ten minutes after ingestion.

Fig. 4 (case 4)—Ileal spasm.





Tracing of spastic area of ileum.

Idiopathic steatorrhœa, suggested by the small-gut pattern, was excluded by the normal fat-balance and lack of response to folic acid. We favoured a diagnosis of intestinal allergy but were disappointed by the failure of appropriate therapy.

CASES WITH CONSTIPATION

Case 4.—Miss D, aged 33, buyer for a large business concern, said that for five years she had been subject to attacks of epigastric or lower abdominal pain, sometimes radiating to the sacrum and down the front of both thighs. This was accompanied by anorexia, nausea, headache, sweating, malaise, abdominal distension, and dysuria. These attacks often, but not invariably, coincided with her menses, which were very irregular. Each attack had lasted from one to three weeks; they were lasting longer and becoming more severe. At first she had had diarrhœa with pale stools, but obstinate constipation had gradually become a feature of the attacks, and any bowel action enhanced the pain. She had had a ventrisuspension and appendicectomy in 1946.

Under observation by us during an attack she had pyrexia of 99°–101°F, blotchy erythema of her face, and distension and tenderness of the lower abdomen, particularly at McBurney's point. At times portions of her transverse, descending, or sigmoid colon became spastic and tender. The following investigations were normal or negative: complete blood-count, E.S.R., skin tests for allergy, intradermal histamine sensitivity test, catheter specimen of urine, twenty-four-hour specimen of urine for tubercle bacilli, bacteriology of stools, gynæcological examination under anæsthesia, plasma-proteins, serum colloidal gold, serum alkaline phosphatase, urinary 17-ketosteroids, blood agglutinations, chest radiography, intravenous pyelogram, barium enema, Wassermann reaction and Kahn test of blood, and examination of cerebrospinal fluid. A barium meal showed clumping, stasis, and spasm in the upper ileum (fig. 4), and this spasm was still present six months later.

Her personality was immature, and one attack was complicated by hysterical paralysis of the left lower limb. This disappeared under psychotherapy, but her attacks continued to get worse. Finally, after an especially long attack when she had lost over 1 stone in weight and her condition was deteriorating and giving rise to anxiety, laparotomy was done; but no organic disease was found and the attacks have continued.

In this case constipation has superseded diarrhœa as the attacks have become longer and more severe. These may be associated with menstruation, and it is noteworthy that a bad attack tends to be followed by a period of about three months during which there is a spontaneous remission, together with amenorrhœa.

Case 5.—Miss E, aged 24, holding a responsible secretarial post, had had acute gastro-enteritis in 1947. Ever since

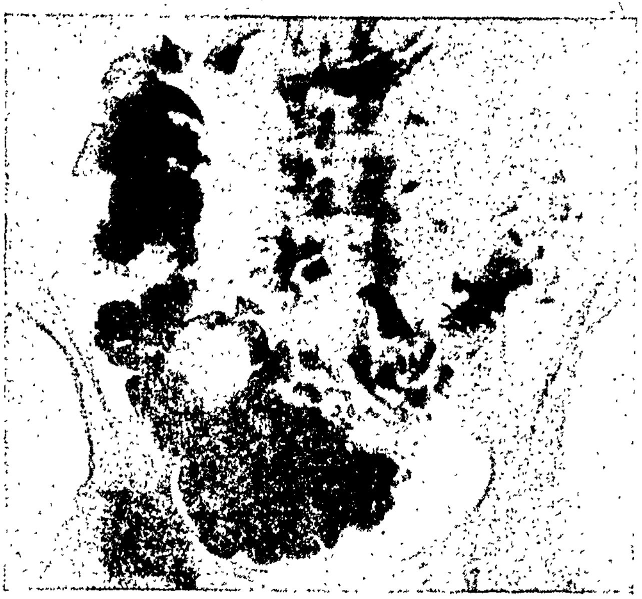


Fig. 5 (case 5)—Clumping and mucosal thickening in small intestine.

then she had had recurrent attacks of dull peri-umbilical *pain radiating to her back, worse during menstrual periods* and accompanied by nausea and flatulence. She had always been constipated.

On examination the only abnormal finding was a loud intestinal splash on movement, a phenomenon which the patient herself had observed and which she stated was always more noticeable after taking liquids. She was an intelligent girl with a bright and cheerful outlook. A barium meal showed what appeared to be a large duodenal polyp, and the meal was still present in the transverse colon one hundred and ten hours after ingestion. Treatment to relieve her *constipation failed to improve her pain.*

When a second barium meal three months later indicated that the "polyp" had become larger, a laparotomy was performed. There was no polyp, the radiological appearances being due to a diverticulum, with a raised margin, arising posteriorly from the first part of the duodenum. This was not considered responsible for her symptoms; so the abdomen was closed.

A year later the symptoms remained unchanged. Skin sensitivity tests were positive to mixed inhalants, and negative to intradermal histamine 1 : 10,000. A histamine test-meal, bacteriological examination of stools, and glucose tolerance were all normal. It was thought that the symptoms might be due to appendicitis; so appendicectomy was performed. *The appendix was normal, and the operation produced no improvement.*

Eighteen months after she had first consulted us, radiological *examination of the small intestine showed clumping and mucosal thickening* (fig. 5), and a reasonable basis for her symptoms had at last been established.

Diverticula are rare in the first part of the duodenum (Golden 1949) and only occasionally produce symptoms (Spriggs and Marxer 1925, Bockus 1944). Apart from the diagnostic difficulties, this case is of interest as being the only one in our series where constipation was associated with demonstrable intestinal delay.

Case 6.—Miss F, aged 42, a Civil Servant, was well adjusted despite a rigid immature personality and chequered history. Abdominal pain had been persistent since she was 23, when appendicectomy had afforded no relief. A second laparotomy at 37 showed no abnormality. At 40 a third laparotomy had revealed tuberculous glands in the ileocæcal region. The abdominal pain was generalised, subject to spontaneous exacerbations and remissions, and was aggravated by defæcation. Constipation was marked. Other symptoms included sacral backache, frequency of micturition, indifferent appetite, nausea, flatulence, and severe abdominal distension. In addition she had asthma, urticaria, and allergic rhinitis; *she was subject to dysmenorrhœa, and in winter her peripheral circulation was poor.*

Under observation she ran an intermittent temperature up to 99°F. Her abdomen was extensively scarred, distended, and tender. E.S.R., complete blood-count, basal metabolic rate, plasma-cholesterol, catheter urine, barium enema, radiography of spine, and fat-balance were all normal. Skin sensitivity tests were positive to mixed inhalants. Although the small-gut pattern was normal, barium reached the cæcum twenty-five minutes after ingestion; follow-through examination of the colon was normal. *Anti-histamines, though very effective for her allergy,* did not help her abdominal pain, and there has been no response to measures designed to relieve the constipation.

This is the only patient in the series with a normal small-gut pattern. *It is interesting and unexpected to find constipation associated with hypermotility* of the small intestine, the time of passage of barium here being less than half the normal minimum of 1 hour (Golden 1945, Shanks and Kerley 1950).

Once the significance of the symptoms was appreciated, it became possible, on clinical grounds alone, to pick out cases from the general mass of dyspeptics attending the clinic, as in the following case:

Case 7.—Mrs. G, aged 36, had had intermittent attacks of abdominal pain, lasting four or five days, since the age of 14. She had never been pregnant and at 32 she had had bilateral tubo-ovarian masses and her appendix removed. The pain was lower abdominal, cramping, and radiating into either groin, to the sacrum, or down the left thigh. It was accompanied by flatulence, distension, frequency of micturition, and constipation, and was sometimes relieved by the passage of a loose stool. The patient had dysmenorrhœa. Clinical examination was unremarkable. A tentative diagnosis of ileal dysfunction was made, and a barium meal showed some 2 inches of severe spasm in the distal ileum (figs. 6 and 7).

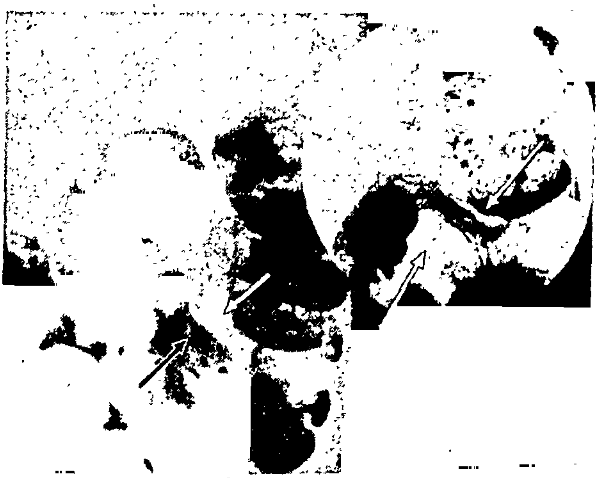

Fig. 6 (case 7)—Intense spasm for 2 in. in distal ileum.

DIAGNOSIS

The main features of the 7 cases reported are:

(1) All were in women who had never been pregnant and whose symptoms had begun during the childbearing period, the length of history averaging *more* than nine years. Dysmenorrhœa was usual.

(2) All the patients had abdominal pain, poorly localised, often radiating to the sacrum, groins, or down the front of the thighs. The pain tended to be aggravated by menstruation and defæcation, but was unaffected by food, holidays, antispasmodics, or rest in hospital.

(3) All had disordered bowel action, abdominal distension was commonly severe, and nausea was frequent.

(4) All were energetic and over-conscientious, with average to good intelligence. They held fairly responsible jobs. Their personalities were immature but they had adapted well to their life situations.

(5) All had had laparotomies for their symptoms, and in none had any organic change been found in small or large bowel.

(6) Clinical examination revealed abdominal distension and tenderness with variable spasticity of the colon. Radiography of the intestines showed spasm, mucosal thickening, hypermotility, or a deficiency pattern, the ileum being consistently affected.

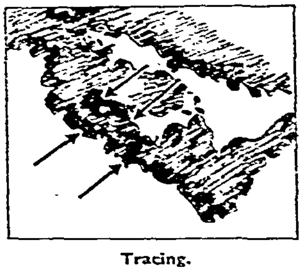
(7) Inconstant features included: pyrexia (4 cases during the attacks), bladder disturbances (5 cases), evidence of poor peripheral circulation (3 cases), and allergic manifestations (3 cases).

Many of these points have been made by Ryle (1928), Spriggs (1931), Hardy (1945), or Bockus (1944) in their writings on colon spasm: and, although Bockus states that colon spasm is often accompanied by motor disturbances of the small intestine, the part played by the small intestine has not been defined further. The points which are significant in the diagnosis of ileal dysfunction and which have not previously been emphasised are the diffuseness of the abdominal pain, the pain in the groin, the distension, the radiological appearances in the small intestine, and the failure of holidays, rest in hospital, psychotherapy, or antispasmodics to have any effect. So far we have found this syndrome only in single, barren, or unhappily married women.

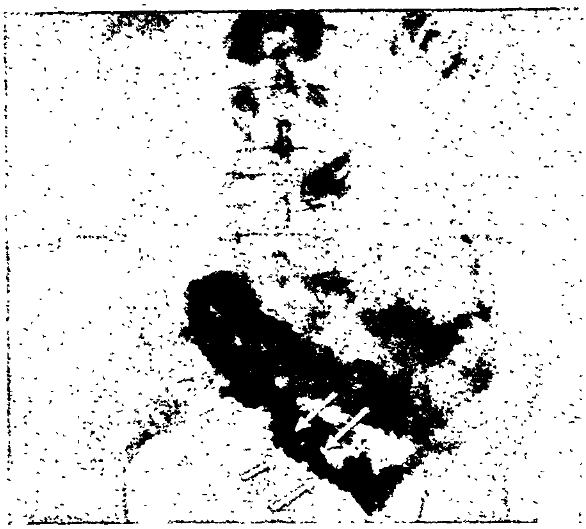
In our experience these cases do not fall into the pattern we have come to recognise as typical of colon spasm. In the same three years 5·5% of the new cases attending the clinic were diagnosed as colon spasm. Males and females, average age 36, were affected in the proportion 6 : 5. These patients had intermittent pain, often mimicking a peptic ulcer in its behaviour, localised to a palpably spastic segment of colon, sometimes associated with constipation, rarely with diarrhœa. They had no allergic manifestations, but overwork and anxiety were often precipitating factors. Relief with a holiday was usual, and the patients responded almost invariably, after reassurance, to antispasmodics and sedatives.

It seems likely that some degree of colon spasm is present in the cases under discussion, but that, when the ileum is involved, the ileal dysfunction tends to dominate both the clinical picture and the response to treatment.

Fig. 8 (case 8)—Abnormal mucosal pattern at junction of proximal two-thirds with distal third of ileum, site of tenderness.



Tracing.



Thus the two syndromes are generally distinct. We have, however, seen one patient presenting the features of small intestinal dysfunction at the same time as those of colon spasm:

Case 8.—Mrs. H, divorced, aged 52, departmental secretary in a large hospital, had had intermittent lower abdominal pain for nineteen years, ever since acute gastro-enteritis. Other symptoms included anorexia, distension, flatulence, nausea, and a worsening of her habitual constipation during the attacks. The attacks were less frequent on holiday and were sometimes precipitated by worry and fatigue. She had had dysmenorrhœa until a subtotal hysterectomy for fibroids in 1945. Her extremities became cold and numb in winter. She was of a highly strung and anxious disposition.

On examination, parts of the ascending and descending colon were distended, and a barium enema showed mild colon spasm. A complete blood-count, E.S.R., and bacteriological examination of stools were all normal. A barium meal showed mucosal thickening of the ileum and an abnormal pattern (fig. 8) at the site of the tenderness. With psychotherapy, antispasmodics, and sedatives the attacks, although still troublesome, have become shorter and less frequent.

This case illustrates very well how the pattern of ileal dysfunction may occasionally overlap that of colonic dysfunction to produce a mixed clinical picture. On the one hand, the patient had a mild anxiety state, her symptoms were aggravated by worry and fatigue, and a barium enema showed colon spasm: she had no allergic manifestations or pyrexia. On the other hand, her pain and tenderness were not localised to the colon, which was not palpably spastic she had radiological changes in the small intestine, and her symptoms were only partially relieved by a holiday, reassurance, and antispasmodics.

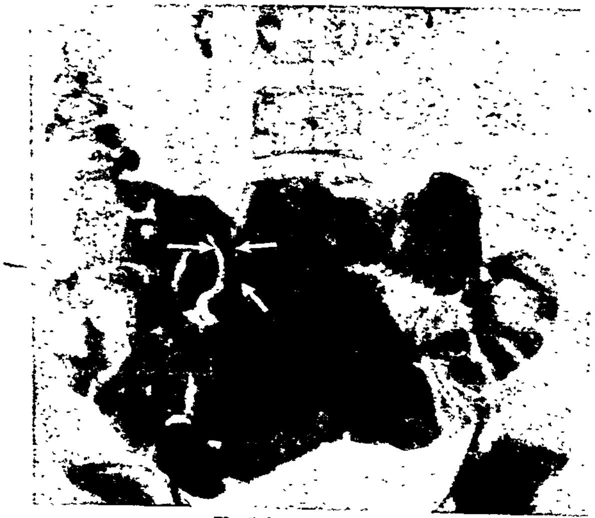


Fig. 7 (case 7)—As fig. 6.

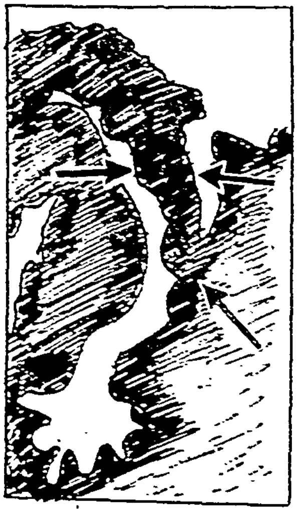

Tracing of spastic area of ileum.

SUMMARY

Functional disorders of the intestine are ill recognised in this country, and, when recognised, the dysfunction has been attributed solely to the colon (colon spasm, irritable colon, functional or motor disorder of the colon).

In our experience many of the features previously described under the heading of

colon spasm are found when the small intestine is involved.

Eight cases (0·53% of 1500 new patients with gastro-intestinal complaints attending a gastric clinic in three years) are described here. They are examples of intestinal dysfunction affecting the ileum in particular.

Colon spasm alone is ten times more common. It is closely related to manifest anxiety, has a well-defined clinical picture, and responds well to reassurance, belladonna, and phenobarbitone.

The ileal syndrome is less obviously psychosomatic in origin, has a more complex symptomatology, and has proved very resistant to treatment.

Although the two syndromes are usually distinct, a case is occasionally seen (case 8) showing some features of both syndromes at the same time.

We wish to thank Dr. Horace Post and Dr. Hector Jones for the radiological investigations, Dr. Arthur Conachy for his psychiatric reports, Mr. Harold Burge for the surgery, and Dr. W. M. Politzer for carrying out the fat-balance tests.

WESTMINSTER CHILDREN'S HOSPITAL

IN this country the commonest cause of lead poisoning in children is the ingestion of paint on woodwork in the home, particularly on cots.

The danger of lead paint to children, well known by manufacturers of nursery furniture, is less well appreciated by the general public. Fathers in particular should be warned; in 4 of the following 5 cases they were unwittingly responsible for the poisoning of their own offspring by applying lead paint to cots.

Titanium, antimony, and zinc oxides have superseded white lead in many pale-coloured gloss paints and enamels used today. It should be noted, however, that some yellow and green varieties still contain 20% of lead chromate.

Compared with other countries, Great Britain is strangely lacking in reports of lead as a hazard to children. Reporting 5 cases Burrows et al. (1951) referred to only 7 other reports during the past sixty years. In addition, 1 due to lead nipple-shields was described by Gordon and Whitehead (1949), and 1 in which the diagnosis was suspected only after death has recently reached the public press: a child, aged 21 months, had chewed lead paint on his cot.

The present 5 cases of plumbism in children bring the number of reports published in this country, during more than half a century, to 19, in which the sources of lead were as follows: painted woodwork (9), nipple-shields (4), toy soldiers (2), fumes inhaled from burning battery casings (2), drinking-water (1), and toilet powder (1).

CASE-RECORDS

Case 1.—A girl, aged 2 years, was admitted to St. Bartholomew's Hospital on July 17, 1951, having been irritable and constipated for three weeks, during which time her face had become thin and pale.

On admission she was drowsy and slightly jaundiced. Respiratory embarrassment was remarkable, with paradoxical inspiratory recession of the epigastrium. Her temperature was 100°F, pulse-rate 140 per minute, and respirations 30 per minute. Her breath was fœtid from ulcerative stomatitis, and her tongue was furred. Apart from the apparent diaphragmatic paralysis no abnormal signs were elicited on examination of the chest. The abdomen was tender to palpation but otherwise normal. There were pain and unequivocal tenderness of the lower limbs, which were held flexed and abducted at the hips. All reflexes were exaggerated and the plantar responses were flexor. The functions of the cranial nerves were unaffected and the ocular fundi normal.

Investigations.—A catheter specimen of urine was pink and contained uroerythrin and urobilin, but no protein or sugar. A moderate excess of white cells was noted in the deposit; there were no red cells or casts, and culture was sterile. A blood-count showed Hb 52%; red cells 3,100,000 per c.mm.; reticulocytes 6%; white cells 18,000 per c.mm. (neutrophils 71%). A blood smear showed punctate basophilia. The red-cell fragility was normal. A blood-culture was sterile. The blood-serum contained total protein 8 g. per 100 ml. (albumin 5·2 g. per 100 ml., globulin 2·8 g. per 100 ml.), blood-urea 58 mg. per 100 ml. The alkali reserve was 70 vols of CO_2%. An indirect van den Bergh test showed bilirubin 1·3 mg. per 100 ml. Thymol turbidity was 3 units. The Takata Ara, Wassermann, Kahn, and direct Coombs tests were negative. The stools contained blood when examined by the benzidine and aminopyrine tests. In the chest radiograph no abnormality was detected, but screening confirmed the clinical diagnosis of diaphragmatic paralysis.

Lumbar puncture produced clear colourless cerebrospinal fluid (C.S.F.) under normal pressure containing 300 red cells, 5 lymphocytes, and 3 polymorphs per c.mm.; protein 45 mg. per 100 ml.; globulin in slight excess; and sugar 90 mg. per 100 ml. The Wassermann reaction was negative.

Lead in bones.—The presence of punctate basophilia prompted a radiographic examination of the bones for lead deposits; bands of increased density were revealed at the growing ends of the shafts of long bones and along the growing margins of flat bones—appearances consistent with lead poisoning. The blood-lead level was 4 µg. per ml. (normal <0·5 µg. per ml.); lead in the urine was slightly in excess of 0·1 mg. per litre (normal <0·1 mg. per litre) (Dr. W. G. Dangerfield).

It was discovered on further inquiry that, for a year, the patient had regularly gnawed her cot, and that her twin sister (case 2) had also acquired this habit but not to the same degree. A history was obtained of other manifestations of pica. The paint, applied to the cot by the father, was examined and found to contain lead.

Treatment, consisting of milk feeds, calcium lactate, and vitamin D, aimed at immobilisation of lead in the bones.

Progress.—Despite penicillin given for the ulcerative stomatitis, and a transfusion of 350 ml. of group O Rh+ blood, pyrexia and tachycardia persisted. Eight days after admission bilateral foot-drop with spasm of the gastrocnemii was evident. Improvement began a week later, the appetite returned, and the child took an interest in her surroundings. At three weeks she weighed 21 lb., having gained more than 1 lb. since admission; her temperature was normal, and repeat screening of the chest showed diaphragmatic contraction. There was now no tenderness of the calf muscles, though wasting was apparent; limitation of dorsiflexion of the foot persisted. Electrical reactions revealed complete degeneration in the extensor hallucis and digitorum longus muscles of both legs; partial degeneration was present in the tibialis anterior and peronei muscles. The upper limbs were unaffected. Physiotherapy, continued for six months, achieved a slow but complete recovery of the affected muscles. On Feb. 19, 1952, a blood-count showed Hb 68%, red cells 3,510,000 per c.mm., and reticulocytes 7·2%; and a blood smear showed mild punctate basophilia. Notwithstanding this evidence of continued toxicity the lead lines in radiographs of the bones were less dense than formerly.

Case 2.—The twin sister of case 1 was admitted to St. Bartholomew's Hospital on July 24, 1951. Other than pica, there was no history of illness. The patient was in the habit of chewing the paint on her sister's cot, and for this reason she was brought to hospital for examination.

On admission she was pale and quiet and looked ill. Her temperature, pulse-rate, and respiration-rate were normal, and no abnormality was detected in the central nervous system. Her urine contained no protein or sugar. A blood-count showed Hb 52%; red cells 3,240,000 per c.mm.; white cells 5700 per c.mm. (neutrophils 46%, lymphocytes 44%, monocytes 10%). Punctate basophilia was seen in a stained blood smear. Similar changes to those found in case 1 were revealed in radiographs of the bones; the inner and outer tables of the skull were involved. The blood-lead level was 2 µg. per ml., and the urinary excretion of lead $<0{\cdot}1$ mg. per litre.

Treatment and progress.—Milk feeds, calcium lactate, and vitamin D were administered; a blood-transfusion increased the hæmoglobin to 68%. The appetite, at first capricious, improved, and when discharged from hospital on Aug. 18, 1951, the patient had gained 2 lb. in weight.

Follow-up.—Six months later the hæmoglobin was 66%, red cells 3,990,000 per c.mm., and reticulocytes 3·1%. Punctate basophilia, though now mild, persisted.

Case 3.—A boy, aged 1 year 8 months, was admitted to the Westminster Children's Hospital on April 22, 1951. For three months previous to admission he had gnawed the paint on his cot and exhibited other manifestations of pica. He had been irritable and constipated for three weeks. Vomiting, at first intermittent, had become copious and projectile.

On examination he was pale, dehydrated, and drowsy. The ocular fundi showed papillœdema, tendon-reflexes were exaggerated, and the plantar responses were extensor.

Lumbar puncture produced clear colourless C.S.F. under increased pressure and containing 4 lymphocytes per c.mm. and 120 mg. of protein per 100 ml.

Other investigations.—The hæmoglobin was 58%, and a blood smear showed a few examples of punctate basophilia. A radiograph of the chest was remarkable in that the angles of the scapulæ were demarcated by dense lines; the growing ends of the long bones also revealed lead lines. The urine contained sugar and 0·9 mg. of lead per litre. The blood-lead level was 6 µg. per ml. On inquiry it was found that the child had ingested paint from his cot and from an outside window-sill, the lead contents of which were 0·85% and 3% respectively; a possible source, which appeared untouched, was red-lead putty containing 7% of lead.

Treatment.—Hydration was maintained with glucose-saline solution, and 10 ml. of 10% calcium gluconate was added to each pint infused. To eliminate the lead remaining in the alimentary canal magnesium sulphate was administered by Ryle's tube; an enema was also given.

Progress.—After two days small milk feeds were taken, the patient becoming more alert. On the advice of the Medical Research Council dimercaprol injections, begun with the object of producing a less toxic lead-dimercaprol compound, were discontinued. Convincing evidence that the compound was less toxic than the lead itself was wanting. Further, the acidosis produced by dimercaprol liberated lead from the bones. It was also suggested that lead in the colon was unlikely to be absorbed in significant degree, and that purgation with magnesium sulphate would again tend to produce a deleterious acidosis. Therapy thereafter consisted of a milk diet, a single dose of 90,000 units of calciferol, and gr. 10 of calcium gluconate with each feed.

Recovery.—Apart from glycosuria, which persisted up to the date of discharge on May 31, 1951, recovery was rapid and uneventful. Two months later the child was healthy; his blood picture was normal, and the radiographic changes in the bones were less evident.

Case 4.—A girl, aged 2 years, was admitted to the Westminster Children's Hospital on Feb. 9, 1952, having been well until five days previous to admission, when cough and coryza developed together with loss of appetite and occasional vomiting. After a transitory remission of her symptoms she was admitted with convulsions, which continued as status epilepticus for twenty-four hours despite repeated intramuscular injections of paraldehyde.

Lumbar puncture produced a clear colourless C.S.F. containing 860 red cells, 15 lymphocytes, and 4 polymorphs per c.mm.; protein 150 mg. per 100 ml.; and sugar 110 mg. per 100 ml. The hæmoglobin was 68%, the white cells numbered 11,000 per c.mm., and the reticulocytes were 0·5%. Punctate basophilia was not reported.

Treatment and progress.—Control having been effected with intramuscular phenobarbitone, on Feb. 12 the convulsions ceased. The child was drowsy and vomited after several feeds, and early papillœdema was detected. A second lumbar puncture produced clear colourless C.S.F. containing 5 lymphocytes per c.mm.; protein 110 mg. per 100 ml.; sugar 84 mg. per 100 ml.; and chloride 730 mg. per 100 ml. The urinary excretion of lead was 0·27 mg. per litre, and radiography of the long bones accorded with a diagnosis of plumbism. A history of pica was elicited on further inquiry, the patient having stripped and eaten the paint off a wall during the past month. A sample of this paint contained lead in high concentration.

Improvement followed treatment with a high-calcium diet and vitamin D; and the excretion of lead in the urine fell to 0·08 mg. per litre in nine days. On discharge on March 14, the patient appeared healthy, with no evidence of cerebral damage ensuing from the encephalopathy. The hæmoglobin was 78%, and slight increase in density of lead lines was shown on repeated radiography of the bones.

Case 5.—A girl, aged 3 years, was admitted to the Westminster Children's Hospital on July 22, 1952. She had been pale and generally unwell for ten months. Her appetite was poor, she had lost weight, and had vomited repeatedly during the week before admission.

On examination she was pale, irritable, and drowsy. Apart from a moderate degree of papillœdema, no abnormality was detected in the nervous system. A radiograph of the skull revealed early separation of the sutures.

Investigations.—Lumbar puncture produced clear, colourless C.S.F. under more than 300 mm. pressure and containing 3 cells per c.mm.; protein 30 mg., sugar 75 mg., and chlorides 720 mg. per 100 ml. The Mantoux 1/1000 was negative. A blood-count showed Hb 50%, and 17,000 white cells per c.mm. with an absolute lymphocytosis. Anisocytosis, poikilocytosis, and hypochromia, but no punctate basophilia, were reported on blood smears. The bone-marrow was normal. Traces of protein and sugar were present in the urine, the deposit contained a few white cells, and the culture was sterile. X-ray examination showed dense lines at the ends of all long bones, and at the angles of the scapulæ. Five days after admission the urinary excretion of lead was 0·29 mg. per litre.

On further inquiry a history of pica was obtained; from the age of ten months she had gnawed her cot which had been repainted four months before admission. The paint was found to contain lead.

Progress.—After lumbar puncture vomiting ceased dramatically, papillœdema subsided slowly, and the patient has since been free from symptoms.

DISCUSSION

Polyneuritis

As a manifestation of lead poisoning in children, polyneuritis, observed in case 1, is much less common than encephalopathy and may occur without any cerebral symptoms whatever.

Ford (1945) states that the legs are usually more severely affected than the arms, and the distal muscles more than the proximal ones. Moreover, there is often definite tenderness of the muscles and even some degree of anæsthesia of peripheral type. Muscular cramps are very common.

Muscle pain and tenderness were undoubtedly present in case 1; but areas of anæsthesia to pinprick were not apparent, though the age of the patient precluded a critical evaluation of sensory changes.

Polyneuritis affecting the diaphragm has been recorded in children by Ford (1945) and Goodwin (1934). The extremities were completely paralysed, and the bulbar muscles involved; a fatal outcome resulted.

The diaphragmatic paralysis in case 1, with recovery after three weeks, seems to be unique.

Radiography in Diagnosis

The importance of radiography in the diagnosis of lead poisoning in children is emphasised by many workers. Heavy transverse bands at the growing ends of long bones may be found, however, in apparently healthy children, especially from the second to the fourth years of age, and these are identical radiographically with the lines which appear during chronic lead poisoning (Caffey 1950).

Endocrine disturbance, particularly hypothyroidism; healing rickets; scurvy; congenital syphilis; Albers-Schönberg disease; poisoning by phosphorus, bismuth, arsenic, and strontium; and excessive medication with vitamin P may all give rise to somewhat similar bands (Stammel 1941).

Evidence of toxicity may persist, notwithstanding regression, as in case 1, or even disappearance of radiological changes in the bones.

Radiographic appearances consistent with the diagnosis of plumbism were present in all five cases; the dense lines at the angles of the scapulæ of cases 3 and 5 were perhaps the most remarkable.

Punctate Basophilia

An increase of stippled cells in the blood, often regarded as the earliest sign of chronic lead poisoning, was minimal in case 3 and absent in cases 4 and 5. It prompted us, however, to suspect the diagnosis in case 1 and to elicit a history of ingestion of lead.

Though not a constant feature, punctate basophilia may also be found in leukæmia and in any severe anæmia (Whitby and Britton 1946).

Diagnosis

That radiographic findings and punctate basophilia alone cannot be recognised as pathognomonic of lead poisoning is evident from the foregoing remarks. The definitive diagnosis must be based on a history of ingestion or inhalation of lead and its demonstration in excessive amounts in the blood and urine.

Pica, a common prelude to plumbism, was exhibited by all five patients. Its diagnostic significance is emphasised by Burrows et al. (1951) and has been mentioned by other workers.

Apart from this symptom, no history of illness was elicited in case 2. The parents considered the patient healthy, and without the knowledge of a case of poisoning in the family admission to hospital and treatment of this child might have been long delayed.

It therefore appears permissible to suggest that, in this country, many similar cryptic cases of lead poisoning probably exist; the paucity of published reports does not reflect the potential danger to children of paint containing lead.

Serious complications, such as encephalopathy, can be averted only by early diagnosis and removal of the source of lead, and by education of the general public to this hazard.

SUMMARY

The potential danger of lead paint to children is emphasised, and 5 cases of poisoning are presented. In 1 complete recovery from diaphragmatic paralysis and bilateral foot-drop was observed. Fits were absent in 2 cases of encephalopathy, and in 1 the C.S.F. was normal.

Polyneuritis, an uncommon manifestation of plumbism in children, is briefly discussed.

Radiography in diagnosis is of value, but more definitive are the history of ingestion of lead and the blood-lead level.

Despite the paucity of published reports it is suggested that many cryptic cases of lead poisoning are probably in existence in this country, most of them arising from the ingestion of lead paint on cots.

We wish to thank Dr. Charles F. Harris for his encouragement and permission to publish cases 1, 2, 3 and 5; Dr. N. O. Richards for allowing us to report case 4; Dr. D. Graham Harvey for the blood-lead estimations; and Dr. D. Hunter for helpful advice.

MANAGEMENT OF HYPOTENSION DURING ANÆSTHESIA

JAMES MCNAUGHT INGLIS
M.B. Leeds, D.A.
SENIOR ANÆSTHETIC REGISTRAR, BIRMINGHAM UNITED HOSPITALS AND BIRMINGHAM REGIONAL HOSPITAL BOARD

THOUGH in the modern practice of anæsthetics the combinations of agents, the methods of administration, and the surgical procedures are numerous and often elaborate, there is a strong case for systematising the treatment of hypotension developing under anæsthesia. This is true especially where the onset is sudden; but, whether the onset is sudden or not, it is generally agreed that such hypotension must be counteracted. Sometimes, indeed, this treatment is more important than continuation of the operation; for without it the patient's cardiovascular system will fail and the operation become pointless.

The two features of the cardiovascular state which are readily and commonly measured are, of course, the blood-pressure (systolic and diastolic) and the pulse-rate.

A rise of blood-pressure during anæsthesia usually indicates maladministration of the anæsthetic rather than a cardiovascular response to physiological disturbances induced by the operation. The progressive hypertensions associated with raised carbon dioxide levels or those associated with anoxia are of this type. They should never occur; but, if they do, the treatment is never empirical but always directed towards removing the precipitating cause. Rare conditions such as phæochromocytoma and pituitary tumours, which may lead to a sudden rise of the blood-pressure, must be borne in mind.

A falling blood-pressure during anæsthesia is, however, a matter of extreme importance, and it is on this response that attention will here be focused. The condition may present in one of three ways:

I. Hypotension with a raised pulse-rate.
II. Hypotension with an unchanged pulse-rate.
III. Hypotension with a slowed pulse-rate.

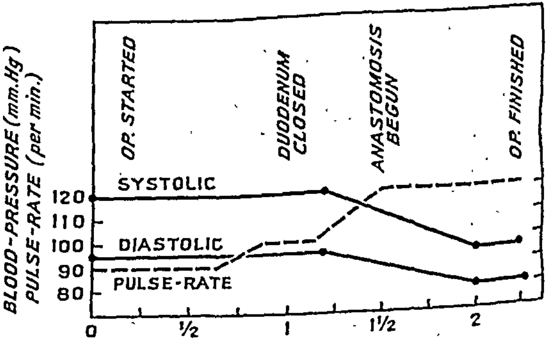

Fig. I—Hypotension with raised pulse-rate (group I) in patient, aged 51, anæsthetised with thiopentone, curare, and oxygen and ether, and undergoing partial gastrectomy. Note pulse-rate began to rise before blood-pressure began to fall. No undue hæmorrhage or trauma was present. No treatment was given for hypotension.

Where the blood-pressure falls suddenly during anæsthesia the pulse-rate at the time will indicate the immediate treatment.

PHYSIOLOGY

The blood-pressure in a normal person is the product of two variables, the cardiac output and the peripheral resistance:

B.P. = C.O. × P.R.

The peripheral resistance is determined by the degree of vasomotor tone, and the cardiac output by a further three variables—namely, the venous return, the force of contraction, and the heart-rate.

From the relationship B.P. = C.O. × P.R. it follows that a sudden fall in blood-pressure must be due either to a sudden falling-off of cardiac output or to a sudden relaxation of vasomotor tone in the peripheral circulation, or to both. There are therefore four physiological disturbances which may lead to acute hypotension:

(1) Reduction in vasomotor tone (peripheral resistance).
(2) Reduction in venous return
(3) Reduction in force of contraction } (cardiac output).
(4) Changes in heart-rate

In the normal person a slight alteration in either the cardiac output or the peripheral resistance will be met by some reflex compensatory mechanism, and no recordable change in the blood-pressure will be seen. It is only when these compensatory mechanisms either break down or become fully expended that the signs of circulatory collapse become evident. The compensatory mechanisms which play the greatest part in maintaining a normal blood-pressure in the face of impending hypotension are increasing heart-rate and increasing peripheral vasoconstriction.

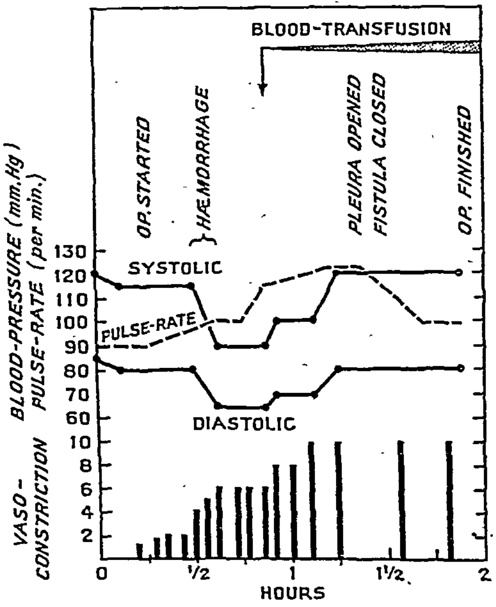

Fig. 2—Hypotension with raised pulse-rate (group I) in patient, aged 37, anæsthetised with thiopentone, gas-and-oxygen, and curare, and undergoing postpneumonectomy thoracoplasty and closure of fistula. Hæmorrhage occurred after $^1/_2$ hr. and accentuated fall of blood-pressure. Note response to blood-transfusion. Vasoconstriction was measured with a digital plethysmograph.

HYPOTENSION WITH A RAISED PULSE-RATE
(Group I)

Figs. 1 and 2 show changes in pulse-rate and in blood-pressure during two operations.

In fig. 1 it is seen that after 40 minutes there was a rise in pulse-rate, followed some 30 minutes later by a progressive decline in blood-pressure. This is a well-known and characteristic response, which may occur where there is no undue anæsthetic depression or maladministration, and where there is no great surgical trauma or hæmorrhage—though its onset may be hastened or precipitated by such factors.

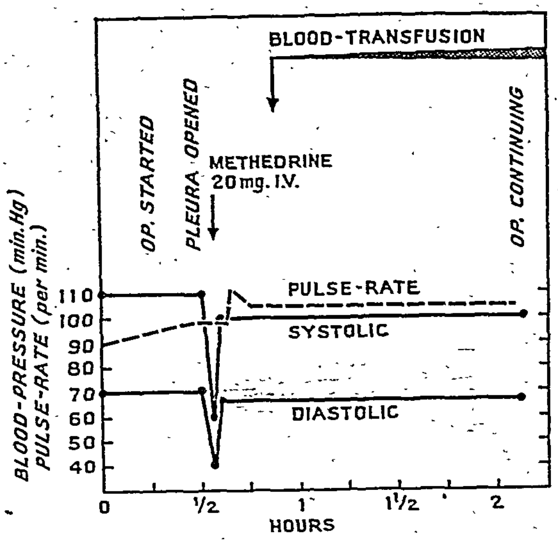

Fig. 3—Hypotension with unchanged pulse-rate (group II) in patient, aged 58, anæsthetised with thiopentone, curare, and gas-and-oxygen, and undergoing transthoracic gastrectomy. Note response to intravenous methedrine 20 mg. Blood-transfusion was begun after 50 minutes in anticipation of group-I response, because pulse-rate had begun to rise.

Fig. 2 shows a similar type of response with the vasoconstriction recorded by means of a digital plethysmograph. Vasoconstriction began before the pulse-rate started to rise, and after 30 minutes the blood-pressure fell sharply as hæmorrhage took place. The heart-rate increased progressively, and so did the degree of vasoconstriction; but these two mechanisms, although they prevented further fall in the blood-pressure, did not restore it to normal. Blood-transfusion was instituted after 15 minutes' hypotension, and gradually the blood-pressure returned to normal, while the pulse-rate eventually decreased. The vasoconstrictor tone was maintained but did not increase further, once the transfusion became effective.

The explanation of this group-I response is physiological. Refer to the complex B.P. = C.O. × P.R. The cardiac output becomes reduced, largely because of the reduction in venous return, which occurs in any curarised or otherwise relaxed person whose active respiratory movement is depressed. There is a compensatory increase in heart-rate together with a compensatory increase in vasoconstriction. These two factors combined suffice, for a time, to maintain a normal blood-pressure. After a variable period, however, the compensatory mechanisms become fully expended and the blood-pressure begins to fall.

The venous return during anæsthesia has in the past received less than its share of attention. In modern anæsthetic practice the use of relaxant drugs produces a person whose muscle tone is, on occasion, virtually nil and whose respiratory excursion and efforts are minimal, being often manually assisted by some degree of positive pressure during inspiration. The venous return depends largely on muscle tone and the intrathoracic negative pressure during inspiration, and under such conditions it will inevitably decrease, with consequent reduction in cardiac output.

One other point should be emphasised. Among the general pharmacological effects of anæsthetic drugs is the decrease of peripheral vasomotor tone, either by direct peripheral action or by medullary depression. In the deeper planes of anæsthesia, therefore, the compensatory vasoconstriction discussed above may not occur, and hypotension will therefore come on earlier. On the other hand, if active vasodilatation occurs as a result of anæsthesia, it may happen that the peripheral blood-flow, and therefore the venous return, is enhanced, with the result that there is less tendency for the cardiac output to fall off. The physiological balance is at all times the deciding factor. If the relaxant drugs are used, *and only light anæsthesia is maintained,* this effect will not become evident so readily.

Whatever the exact mechanism of this response, the treatment is always to improve the cardiac output. The most physiological means of doing this is to increase the venous return by posture or by infusion of whole blood or whatever blood substitute is favoured. The response to blood-transfusion is shown in fig. 2.

This type of response is well known to all clinical anæsthetists, and its mode of onset is only rarely as acute as that of the hypotensions to be described below *(groups II and III). Such an acute onset may, however,* be seen. Immediately after induction of anæsthesia there may be acute cardiovascular collapse, with severe hypotension and tachycardia. The basic physiological explanation is the same as before: the falling blood-pressure is the direct result of a lowered cardiac output. The only difference in this instance is that the precipitating cause of the lowered output is different. Instead of the decreased venous return we now have a diminished force of contraction, perhaps due to overdosage with or without medullary depression, or perhaps due to disease of the myocardium. The exact mechanism is of less consequence than the immediate treatment. This treatment is, in principle, the same as before—namely, to improve the cardiac output. In such an emergency intravenous therapy may be too slow a remedy, and it is in such instances that cardiac analeptics and medullary stimulants, such as adrenaline and nikethamide, have their place in anæsthesia.

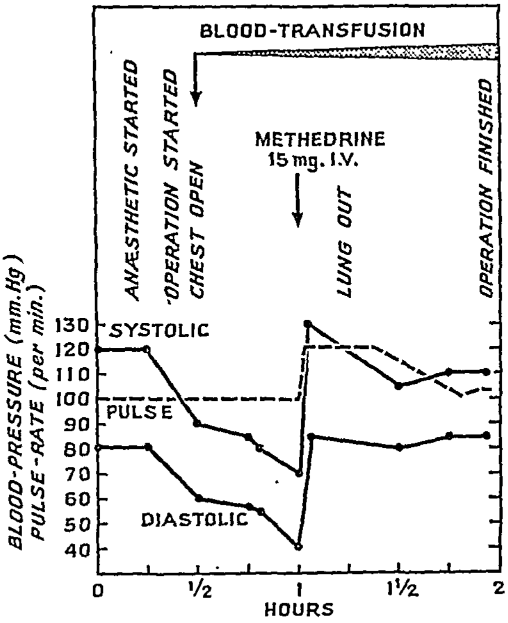

Fig. 4—Hypotension (less acute than in fig. 3) with unchanged pulse-rate (group II) in patient, aged 48, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, and undergoing pneumonectomy. Note absence of response to blood-transfusion and good response to intravenous methedrine 15 mg.

The group just described is an extensive one, with many factors at work. The treatment, however, rests on a single physiological factor—the cardiac output. We may, in fact, say:

> Where anæsthetic hypotension is associated with an increase in pulse-rate, the treatment should be directed towards increasing the cardiac output.

In this type of response the use of vasopressor agents, such as 'Methedrine' and *l*-noradrenaline, is unsound. Compensatory vasoconstriction takes place quite automatically, and it is only when this mechanism becomes exhausted that the hypotension appears as a clinical sign of failure. The degree of vasoconstriction present in the patient at this time will already be high, and pure vasoconstrictor drugs will do little to increase it.

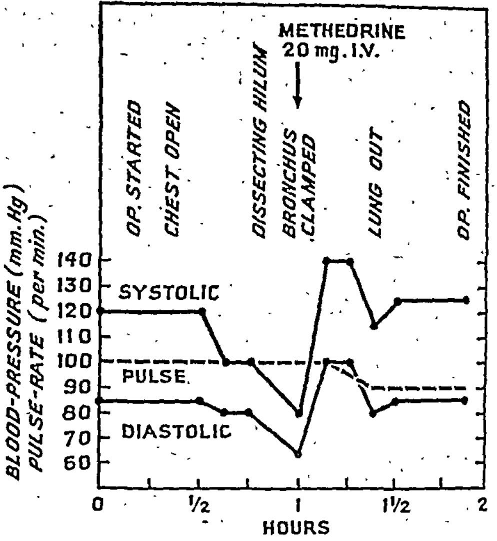

Fig. 5—Hypotension with unchanged pulse-rate (group II) in patient, aged 54, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, and undergoing pneumonectomy. Note hypotension took 30 minutes to become fully developed and steady pulse-rate fell when vasoconstriction, effected with intravenous methedrine, improved venous return.

HYPOTENSION WITH AN UNCHANGED PULSE-RATE
(Group II)

Increasing the heart-rate will not improve cardiac output unless the venous return to the right side of the heart is increased sufficiently to keep the myocardium adequately stretched during the shortened diastole.

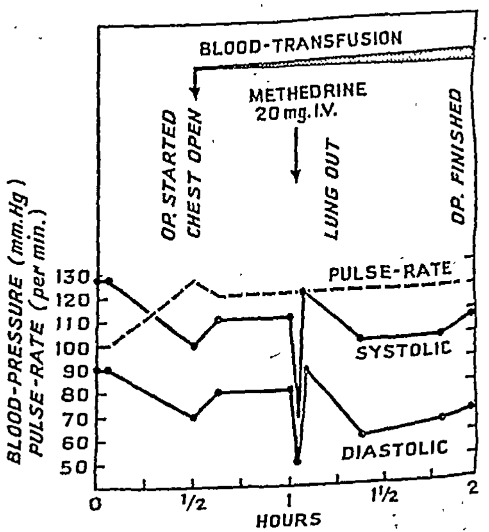

Fig. 6—Hypotension of both group I and group II in patient, aged 47, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, and undergoing pneumonectomy.

The venous return is, as already mentioned, maintained by muscle tone and respiratory movement, and improved by vasoconstriction. In the normal person the degree of vasomotor tone in the arteriolar bed will therefore influence the venous return.

Reduction in vasoconstrictor tone will lead to a lowering of the pressure within the peripheral circulation and hence to a reduced pressure head behind the venous flow. The venous return will therefore decrease, and so, in consequence, will the cardiac output. Increase of heart-rate is therefore not seen, for without adequate venous filling it will not improve output.

Fig. 3 is the record of cardiovascular changes in a man, aged 58, undergoing thoracotomy for total resection of the stomach. After the pleura was opened, the systolic and diastolic blood-pressures fell sharply, but the pulse-rate remained at its previous level. This hypotension could not be due to a primary falling off of cardiac output, since compensatory vasoconstriction would have occurred, and the resulting improvement in venous return would have led to an increase in heart-rate. Administration of a vasoconstrictor drug (in this instance intravenous methedrine 20 mg.), produced the necessary increase in vasomotor tone, and the blood-pressure returned to a more normal level. Some tachycardia was seen and was perhaps due to the slight cardio-stimulant action of the methedrine.

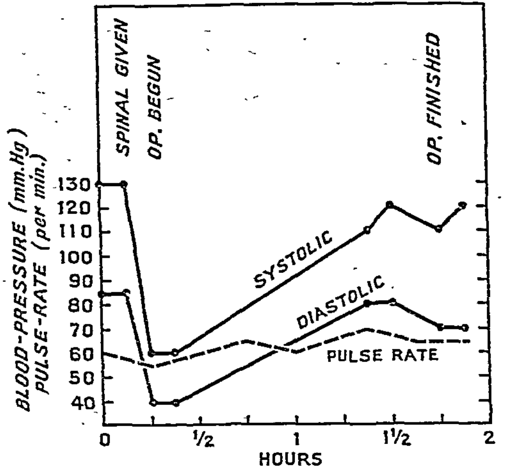

Fig. 7—Severe hypotension induced by spinal anæsthetic (heavy 'Nupercaine' 2 ml.) in patient, aged 69, anæsthetised with thiopentone, gas-and-oxygen, and spinal nupercaine, and undergoing herniorrhaphy. No vasoconstrictor was used.

Fig. 4 illustrates the effect of treating this type of response with blood-transfusion. The blood-pressure began to fall shortly after the induction of the anæsthetic, but intravenous blood did little to combat it. The pulse remained steady. After 50 minutes a vasoconstrictor drug was given with an immediate response, which was maintained for the remainder of the operation.

In the first example the sudden fall in blood-pressure may have been due to the opening of the pleura with its possible attendant complications. In the second example the anæsthetic or its method of administration may be suspect. Figs. 5 and 6, however, show how this response may appear either suddenly or less acutely during an operation without any apparent precipitating factor.

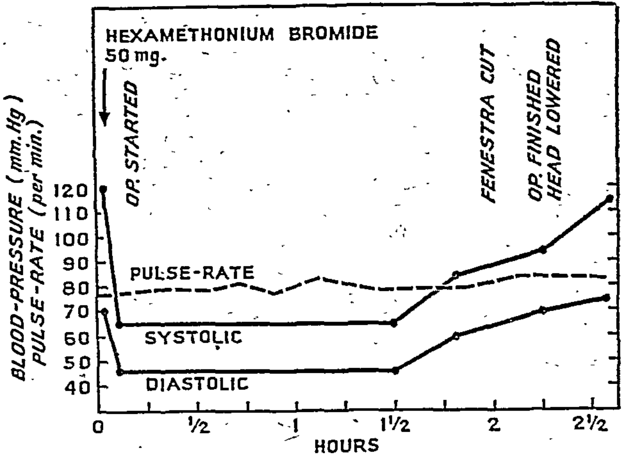

Fig. 8—Hypotension artificially induced with hexamethonium bromide in patient, aged 46, anæsthetised with thiopentone, gas-and-oxygen, and 'Trilene,' and undergoing fenestration. Note pulse-rate reasonably steady.

Other examples of this type of response are seen with high spinal block, or when "controlled circulation" is used with the aid of hexamethonium or similar hypotensive agents.

Fig. 7 illustrates the response to spinal block where no vasopressor is used. The blood-pressure was considerably reduced by sympathetic paralysis, but carbon dioxide retention and anoxia were avoided and little hæmorrhage took place; hence the pulse-rate did not increase. Clearly the use of a vasopressor in this instance would have restored the blood-pressure to a more reasonable level.

Fig. 8 shows hypotension caused by hexamethonium bromide. The blood-pressure was considerably lowered but again the pulse-rate remained steady.

Both spinal block and hexamethonium lead to either a localised or a generalised vasodilatation. In both cases the peripheral resistance *and* the cardiac output are reduced and hypotension results. Restoration of the vasomotor tone restores normal vascular tone, and circulatory efficiency is once more produced. Hence:

> Where anæsthetic hypotension is unaccompanied by any alteration in heart-rate the initial treatment should be directed towards improving vasoconstrictor tone.

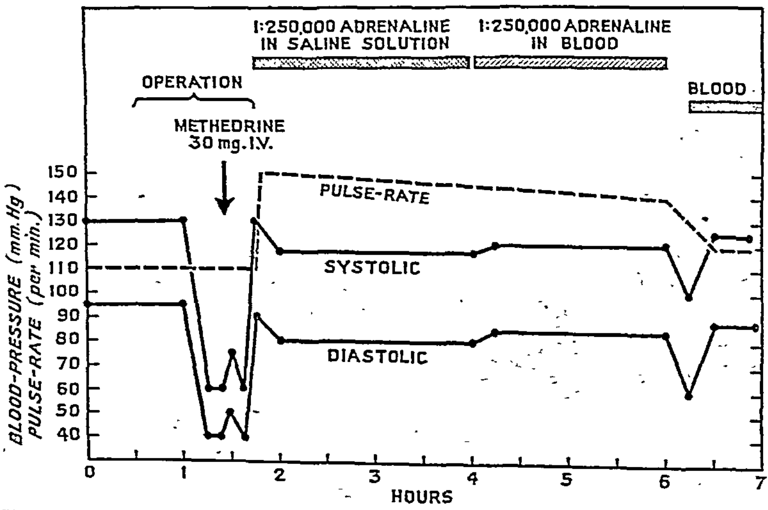

Fig. 9—Treatment of peripheral circulatory collapse with adrenaline drip in patient, aged 42, anæsthetised with heavy nupercaine (spinal) 1·8 ml., thiopentone, and gas-and-oxygen, and undergoing laparotomy and colostomy. In spite of severe fall in blood-pressure towards end of operation, pulse-rate remains steady until adrenaline produces tachycardia.

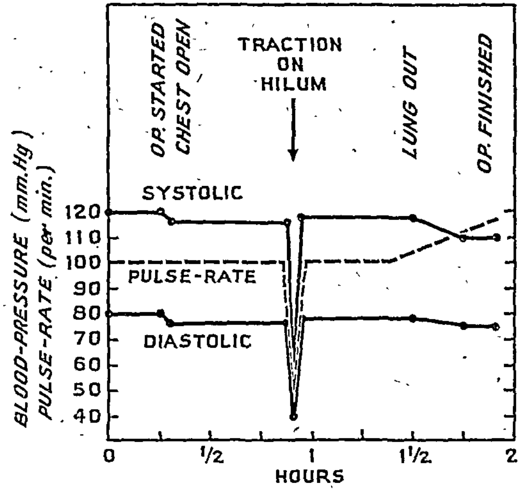

Fig. 10—Transient hypotension with slowed pulse-rate (group III) caused by traction on hilum of lung during pneumonectomy in patient, aged 24, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare. No treatment necessary.

Sometimes it does seem necessary to maintain the vasoconstrictor therapy for a long time. The term "peripheral circulatory failure" has been applied to this same picture when the hypotension is prolonged. Repeated injections of methedrine or adrenaline or *l*-noradrenaline by intravenous drip may be required. Fig. 9 illustrates this type, a case of this kind in which adrenaline was used. *l*-Noradrenaline appears to be more effective and to lead to less tachycardia.

HYPOTENSION WITH A SLOWED PULSE-RATE
(Group III)

This is the so-called "vagal overaction" group.

Since the vagus is the cardio-inhibitory nerve, stimulation of the efferent motor side, or of the afferent sensory one, may lead to slowing of the heart or even to actual inhibition. Hypotension associated with bradycardia may result from vagal stimulation from any cause.

The physiological mechanism is threefold. Vagal stimulation may lead to bradycardia, lessened force of contraction, or peripheral vasodilatation due to inhibition of the vasomotor centre. The fact that any one of these factors can by itself lead to hypotension by disturbance of the B.P. = C.O. × P.R. complex will be appreciated from what has been said before. The combination of all of them acting together, or of the first two only, will on occasion make treatment necessary.

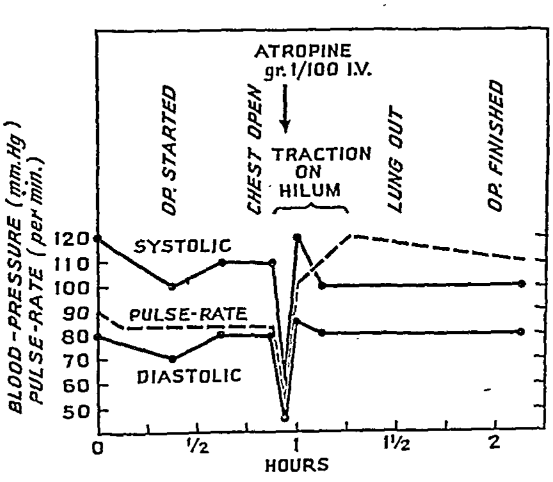

Fig. 11—Hypotension with slowed pulse-rate (group III) caused by traction on hilum of lung during pneumonectomy in patient, aged 37, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, showing response to atropine.

Figs. 10 and 11 illustrate this vagal overaction where the precipitating cause was traction on the hilum of a lung. Fig. 12 illustrates the same phenomenon where the initial trauma was dissection of the œsophagus.

In the case illustrated in fig. 10 the traction was transient and cessation of the stimulus led to a return of the pulse-rate and blood-pressure to normal. In the case illustrated in fig. 11 the traction was maintained longer, but pharmacological vagal block with intravenous atropine restored the picture to normality very rapidly, and indeed there was tachycardia when the vagal influences were removed. An intravenous dose of gr. $^1/_{100}$ seems to be sufficient to inhibit the vagal influence in such instances.

The existence of a slow heart-rate from the beginning, either before induction or during the progress of the operation, suggests that the patient may be more likely to exhibit these vagal responses. Moreover this vagal overaction is seen mostly in lightly anæsthetised patients; and, since it is common practice today to maintain these light planes of anæsthetic depression when relaxant drugs are being used, it will develop more often than in the past.

The stimulus which precipitates these vagal manifestations need not, of course, be intrathoracic: indeed direct mechanical stimulation of the vagus nerve rarely leads to this response. It is usually the afferent nerves which bring about reflex vagal hypotensions. The afferents may be direct vagal ones—e.g., from the lung hilum—or they may be visceral afferents from the abdomen and pelvis, and this response has been seen as a result of cutaneous stimulation in a highly susceptible person. Hence:

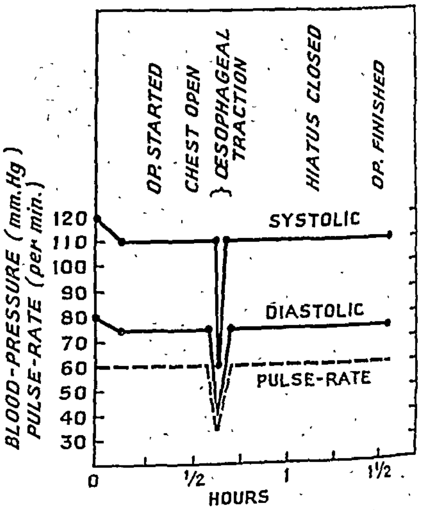

Fig. 12—Transient hypotension with slowed pulse-rate (group III) in patient, aged 41, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, and undergoing repair of hiatus hernia. Note initial bradycardia typical of patients who develop this type of hypotension.

> When anæsthetic hypotension is accompanied by a slowing of the pulse-rate, the most effective treatment is pharmacological vagal block.

DISCUSSION

The management of anæsthetic hypotension may be an emergency problem. For this reason I have classified it in the three above-mentioned groups together with the appropriate treatment. Occasionally, however, there is difficulty in allotting a particular response to its correct group. In such cases the most effective line of treatment can only be decided on clinical judgment.

As is to be expected, the picture is sometimes clouded by tachycardia from other causes, but it is not the *absolute* pulse-rate which is important. It is of no great consequence whether the pulse-rate is 80 or 110 at the outset of the operation. What does matter is the fluctuation from the original rate, if and when the

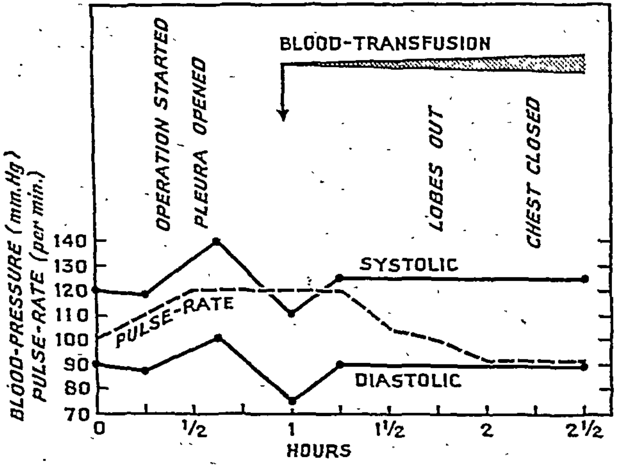

Fig. 13—Atypical form of group-I hypotension in patient, aged 23, anæsthetised with thiopentone, pethidine, gas-and-oxygen, and curare, and undergoing lobectomy. Fall in blood-pressure is preceded by a rise associated with raised pulse-rate. There was no accumulation of carbon dioxide.

blood-pressure begins to fall. It is this *alteration* in rate which gives the clue to the precipitating mechanism and therefore to the best form of treatment.

Some of these responses may be so transient as to be overlooked—as with the vagal traction reflexes. They may appear and pass off and not be noticed unless the pulse-rate is closely observed throughout.

The expression "shock" has not been used. It has been avoided deliberately. The word is confusing and gives no indication of the mechanism of the disturbance. Moreover, it has led in the past, and unfortunately sometimes still leads, to the treatment of all hypotension during operation by blood-transfusion. Such treatment is appropriate only for hypotension resulting from lowered venous return (group I).

Some still believe that, unless bleeding has taken place, transfusion is not called for; but nothing could be further from the truth. There can be few operations necessitating extreme muscular relaxation and lasting an hour and a half or more which do not tax the compensatory vasoconstrictor mechanism of the patient very considerably.

Where there is accumulation of carbon dioxide within the circulation, the blood-pressure may be artificially maintained, and there may even be a rise in blood-pressure. The so-called cyclopropane shock may be explained upon this basis: a raised blood-carbon dioxide level (due to respiratory depression, and perhaps to inefficient absorption in a closed circuit) maintains the patient's blood-pressure until administration is discontinued, but as soon as carbon dioxide is eliminated the patient develops hypotension. Carbon dioxide build-up may also be the cause of the somewhat atypical group-I responses which are sometimes seen (fig. 13).

An alternative explanation of this picture is, however, suggested by the possibility of overcompensation due to excessive vasoconstriction. Whatever the reason, this example serves to emphasise the final point: however many generalisations are made from clinical observation, there is always the need for individual assessment of each case. It may prove the exception to the rule.

SUMMARY

The development of hypotension during an operation under anæsthesia should be regarded as an emergency.

Such hypotension can be divided into three groups: (1) with a raised pulse-rate; (2) with an unchanged pulse-rate; and (3) with a slowed pulse-rate. If the blood-pressure falls suddenly, the patient's pulse-rate at that time indicates the immediate treatment.

Hypotension with a raised pulse-rate is due to reduction of the cardiac output, largely because of reduction of the venous return. So the treatment aims at increasing the venous return by posture or by blood-transfusion. Sometimes the cardiac output is reduced owing to insufficient contraction of the heart, perhaps due to overdosage with anæsthetic. Blood-transfusion would then act too slowly, and treatment should be with cardiac analeptics and medullary stimulants. In both these forms of hypotension the treatment aims at increasing the cardiac output.

Hypotension with unchanged pulse-rate is due to reduction of vasoconstrictor tone. Therefore treatment should be directed towards improving that tone with such drugs as methedrine and adrenaline.

Hypotension with slowed pulse-rate is due to overstimulation of the vagus nerve, when the most effective treatment is pharmacological vagal block with atropine.

I am indebted to Dr. B. L. S. Murtagh for his encouragement and helpful criticism in the preparation of this paper.

PRIMARY CLOSTRIDIAL PNEUMONIA

REPORT OF A CASE

A. E. O'Donnell
M.B.E., M.B. Dubl.

SURGICAL CLINICAL ASSISTANT, BROMLEY HOSPITAL, KENT

Clostridial infection of the lungs and pleural cavity is common in war surgery (it accounted for 10% of all infected hæmothoraces in the 1914–18 war) and not uncommon in civilian practice, when it occurs either as a secondary infection in chronic pulmonary disease or as an intrapleural infection following lobectomy. But I have not been able to find any record of a primary clostridial pneumonia which behaved as a lobar pneumonia, without lung gangrene, followed by clostridial empyema.

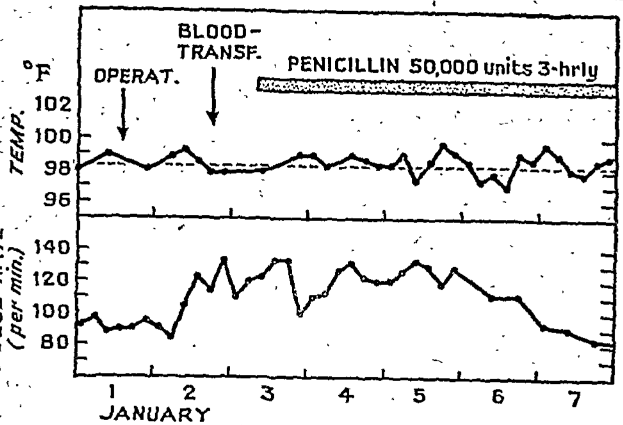
CASE-RECORD

Miss A, aged 52, was admitted to Bromley and District Hospital on Dec. 8, 1947, with duodenal ulcer of 15 years' duration, for which she had had previous medical treatment. She had also had nasal catarrh for some years, for which she had undergone submucous resection of the nasal septum, with poor result. In the past year she had vomited frequently, sometimes once or twice a day, and radiography after a barium meal on Oct. 28, 1947, suggested that there was an old duodenal ulcer with pylorospasm or stenosis. It was thought that partial gastrectomy would be necessary; but, owing to the nasal infection, medical treatment was continued for three weeks. The vomiting became less, but the pain increased in intensity, and it was decided to operate.

A blood-count on Dec. 30, 1947, showed red cells 4,850,000 per c.mm., Hb 93%, and colour-index 0·96.

Operation and Postoperative Course

On Jan. 1, 1948, a Polya type partial gastrectomy with antecolic anastomosis was done. At the end of the operation and throughout the following night the patient's condition was excellent, and at 8.30 A.M. on Jan. 2 her pulse-rate was steady at about 86. She then began to look ill, and her pulse-rate rose rapidly, reaching 120 by noon. Since only a little blood had been aspirated through the Ryle's tube, intra-abdominal hæmorrhage was suspected, and a pint of group-O4 blood was transfused, but a blood-count later on the same day showed red cells 4,789,000 per c.mm., Hb 88%, and colour-index 0·92. The blood was Rh-positive.



Association of rapid pulse-rate with low temperature.

By the morning of Jan. 4 the patient had a fulminating pneumonia at the left base. Parenteral penicillin 50,000 units three-hourly was prescribed, with sulphamerazine gr. 2 four-hourly for twelve hours and then gr. 1 four-hourly.

Course of Pneumonia

The temperature at this stage rarely rose above 99°F, and the patient's general condition was regarded as very grave. The accompanying figure shows the disparity between the pulse-rate and the temperature.

Jan. 8.—A blood-count showed red cells 3,000,000 per c.mm., and Hb 62%, but the general condition was improving steadily.

Jan. 11.—Penicillin discontinued.

Jan. 12.—A blood-count showed red cells 1,480,000 per c.mm., and Hb 34%. Two pints of group-*O4* blood was transfused; but two days later a blood-count showed only moderate improvement: red cells 2,500,000 per c.mm., Hb 50%, and white cells 45,000 (polymorphs 88%). A further two pints of blood was given.

Jan. 18.—The pulse-rate, which had fallen to about 100 on the fifth postoperative day, now rose again and the temperature began to swing. There was bronchial breathing at the left base, with stony dullness and tenderness over the ribs. Treatment with parenteral penicillin 100,000 units three-hourly was begun again.

Jan. 24.—Aspiration produced 20 ml. of opalescent straw-coloured fluid, for which was substituted 100,000 units of penicillin. Culture of the fluid yielded a scanty growth of *Clostridium welchii* sensitive to penicillin.

Jan. 26.—About 150 ml. of stinking pus was aspirated, for which was substituted 350,000 units of penicillin. Culture yielded a profuse growth of *Cl. welchii*. By this time considerable œdema and tenderness had developed in the left chest wall posteriorly, and the patient complained of a good deal of pain.

Jan. 27.—A blood-count showed red cells 3,900,000 per c.mm., and Hb 70%. A fourth transfusion (2 pints) was given. Treatment with anti-gas-gangrene serum, 10,000 units twice daily, was started and continued until Feb. 5. The patient began to cough up thick offensive mucopurulent yellowish sputum. A direct stained film showed many pus cells, gram-positive cocci, and a few gram-positive bacilli. Cultures yielded a fair growth of coliform organisms, hæmolytic streptococci of Lancefield group C, and a scanty growth of *Cl. welchii*.

Jan. 31.—Her condition was deteriorating, the œdema of the chest wall was spreading, and she again complained of pain. A third aspiration produced 150 ml. of similar pus. No penicillin was substituted.

Feb. 1.—There was localised subcutaneous emphysema of the chest wall at the site of the aspiration, and it was feared that the infection had spread to the chest wall, but this disappeared in a few hours, and did not recur.

Feb. 3.—A fourth aspiration produced 40 ml. of pus and 350,000 units of penicillin was introduced. In a search for the original focus of infection a nasal swab was taken which on culture yielded a heavy growth of *Cl. welchii* and a fair growth of coagulase-positive *Staph. aureus* and fæcal streptococci.

Feb. 6.—Despite several attempts at aspiration, no pus was located. Henceforth the patient began to improve rapidly; the pain in her chest disappeared, and her appetite returned. The anti-gas-gangrene serum was discontinued on Feb. 5, and the penicillin on Feb. 13.

Feb. 25.—Patient was discharged to her home.

Follow-up

On March 8 she felt well but "shaky." There was still some discomfort in the left chest which prevented her from inhaling deeply. She could take a normal diet without discomfort, so long as she avoided a heavy meal. Radiography showed that the left lung was mainly clear, with overlying residual pleural thickening and an obscured left costophrenic angle. A nasal swab was negative for *Cl. welchii.*

COMMENTS

It is fairly evident from the bacteriological findings that in this case of clostridial pneumonia the infection came from the nose.

The sudden increase of pulse-rate to 120, accompanied by low temperature (97°–99°F) and intense toxicity, caused some confusion until *Cl. welchii* was identified. It was then seen that the infection followed the general pattern of other clostridial infections.

In eleven days the amounts of hæmoglobin decreased from 93 to 34% and the erythrocyte-count from 4,850,000 to 1,480,000 per c.mm.

Two courses of parenteral penicillin, to a total of 18,500,000 units, and one course of anti-gas-gangrene serum, to a total of 140,000 units, were given. In addition, penicillin 800,000 units was injected into the abscess cavity, and a nasal spray containing 30,000 units per ml. was used four or five times daily from Feb. 4 until the day before discharge from hospital.

Throughout this illness, the partial gastrectomy gave no trouble whatsoever. The patient vomited once only, at the end of four days' sulphamerazine therapy, which was immediately discontinued.

Much suffering to the patient, and anxiety of the doctors and nurses could, I believe, have been avoided if her nose had been swabbed before the operation. The penicillin spray succeeded in eliminating the infecting organism from the nasal discharge at least temporarily. Had this been done preoperatively and supplemented by a prophylactic course of parenteral penicillin, continued through the early postoperative period, she would probably have had an uneventful convalescence.

My thanks are due to Dr. John Keall and Dr. A. C. Glendinning for their keen interest and the considerable amount of work done in the pathological and radiological departments respectively. Also to Mr. W. P. Greening for his persistent advice to avoid, at all costs, open drainage of the empyema cavity.

Preliminary Communication

EXPERIMENTAL DEPLETION OF POTASSIUM IN MAN

More than 97% of the body potassium is intracellular, and deficiency of potassium affects mainly the intracellular compartment. It may result from excessive *loss, deficient intake, or increased need.* An increased need arises when the volume of intracellular fluid is expanded, as with the laying down of glycogen. In this instance there is an increased need for other constituents of intracellular fluid as well, such as phosphate. But when deficiency of potassium arises from simple loss or lack of the ion, it is not clear whether other constituents of intracellular fluid, such as phosphate and water, are lost, to preserve the composition of intracellular fluid at the expense of its volume. Potassium deficiency is usually compensated by entry of sodium into cells and accompanied by alkalosis.

Potassium deficiency has not been much studied by experiment in man. Its clinical significance and the nature and importance of compensatory mechanisms remain ill defined. Black and Milne[1] induced moderate deficiency of potassium by removing potassium from their fluid diet with an exchange resin ('Zeo-Karb 225 Na'). The place of potassium in the diet was taken by sodium. The experiments were perforce of short duration; the deficiency of potassium was largely due to renal losses while the kidney adjusted to the low intake; the intake of sodium was liberal (about 300 mEq. per day).

---

[1] Black, D. A. K., Milne, M. D. *Lancet*, 1952, i, 244.

We have induced deficiency of potassium by eating the resin in H or NH_4 form for 12 or 16 days while taking a normal and constant diet. The deficiency of potassium was largely due to fæcal losses, which exceeded the dietary intake. The intake of sodium was about 200 mEq. daily, and absorption of sodium was partly prevented by the resin.

There were three experiments (F1, W, and F2). The procedure has previously been described.[2]

RESULTS

The results are based on the differences between balances in the control periods and those in the treatment and recovery periods. They are presented cumulatively in the accompanying table. The deficiency of potassium calculated in this way amounted to 338 mEq. in F1, 674 mEq. in W, and 839 mEq. in F2. In W and F2 this would correspond to some 28% of the exchangeable potassium in the body. Although the resin took up some sodium, sodium balance was maintained, because renal conservation of sodium was efficient. On the other hand, an excess of sodium was not available to take the place of potassium. The loss of potassium was accompanied by a moderate acidosis, and the plasma CO_2 fell to 17, 12, and 15 mEq. per litre in F1, W, and F2. The acidosis was possibly due to the loss of cation—i.e., potassium—rather than to a gain of anion resulting from any failure of the kidneys to excrete the excess of anion over cation absorbed from the gut. It was accompanied by the loss of 2 or 3 litres of fluid. Most of this was from cells, as calculated from the chloride balance, the serum-chloride, and the changes in water excretion. There was also some loss of phosphate and of nitrogen. The loss of nitrogen, representing breakdown of protoplasm, accounted for some of the loss of phosphate (see table). In proportion to the composition of intracellular fluid these losses were not of the same order as the loss of potassium; they were of the magnitude seen in acidosis without depletion of potassium. The subjects felt and looked very ill, took their diet with extreme difficulty, and became absent-minded and then confused. Some features, such as thirst, hæmoconcentration, and a raised serum-sodium level, suggested a state of water deprivation, but the changes were not corrected by a free intake of water.

CUMULATIVE BALANCES OF K, N, P, Na, Cl, AND WATER

	At end of resin period			At end of recovery period	
Experiment	F1	W	F2	F1	F2
Duration of period (days)	16	12	16	8	12
K (mEq.)	−338	−674	−839	−122	−692
N (g.)	−18·7	−13·1	−27·1	−18·0	−36
P (g.)	−2·6	−5·1	−3·2	−0·8	−1·3
Na (mEq.)	+346	−98	−28	+748	+855
Cl (mEq.)	+238	−48	−144	+308	+252
Water (litres)	+0·5	−3·0	−3·1	+3·6	+1·8

In protoplasm K (mEq.) : N (g.) : P (g.) :: 2·7 : 1 : 1/15.

When the administration of resin was stopped, sodium and potassium were again available for absorption. Retention of potassium was maximal but limited by the amount available in the diet (38, 36, and 31 mEq. daily); hence deficiency of potassium was present for the duration of the observations. Retention of sodium was maximal for a few days and at first occurred without chloride. Thus sodium entered cells. Within a few days the acidosis receded and the plasma CO_2 rose some 6 or 7 mEq. per litre above control values. This change was the same for the very different amounts of potassium lost in F1 and F2. The loss of nitrogen incurred with resin was not made good during the recovery period, though the intake of protein was adequate (74, 66, and 79 g. daily). The intracellular dehydration was corrected, and loss of phosphate was restored except for a fraction accompanying nitrogen. These changes were followed or accompanied by a gross increase in the volume of extracellular fluid: W, in whom we had had to stop collecting balance data, developed œdema of the legs and face. With the exception that F2 had tetanic carpal spasms for a few days, symptoms were not dramatic in the recovery period. The subjects were morose, apathetic, and tired easily. They still had no desire to eat.

On the day that experiment F2 ended, the subject of the experiment lacked some 600 mEq. of potassium. He did not know this and drove to North Wales. He went hill walking on the same day. He found the mental and physical effort no more than trying, but he was unaccustomedly breathless on going uphill. The only definite electrocardiographic changes in these experiments was the appearance of prominent U waves.

CONCLUSIONS

Depletion of potassium is not necessarily accompanied by an equivalent loss of other constituents of intracellular fluid.

The alkalosis of potassium deficiency may not occur without retention of sodium; even with retention of sodium the alkalosis may be slight, though depletion of potassium is great. Retained sodium enters cells but also causes an increase in extracellular fluid, and œdema may result.

If sodium is retained in place of potassium, symptoms may be neither severe nor urgent, but apathy and anorexia may be prominent. Lack of potassium may limit retention of nitrogen.

The body can lose large amounts of potassium; and, unless potassium salts are given, restoration may be very slow. We agree with Black and Milne[1] that, when possible, the oral route is to be preferred.

We are indebted to the Medical Research Council for a grant for expenses, and to Prof. L. J. Witts in whose department this work was done.

"The theory of probability which was born out of problems that arise in connexion with gambling has become one of the most abstract departments of mathematics. The offspring of a practical need, to ascertain the rules governing the behaviour of collections with a view to manipulating them in ways conformable to our wishes (in short, to make money), the science of probability has transcended its origins and is now pursued for the intellectual satisfactions with which it delights its devotees. In this respect its development has been contrary to that of most of the sciences which, starting from the impulse to find out, are to-day carried on from the wish to modify and control, as the desire for knowledge increasingly gives way to the desire for power."—*Times Literary Supplement*, Aug. 8, 1952, p. 514.

Reviews of Books

Solitude and Privacy

PAUL HALMOS, B.A., PH.D. London: Routledge & Kegan Paul. 1952. Pp. 181. 21*s.*

DOCTORS are enjoined nowadays to study not only the "whole man" but a good part of his environment as well. Those who are conscientious, especially if their interest is in social medicine or psychiatry, can be advised to try Dr. Halmos's book as a good example of the scope, method, and interest of this branch of knowledge. But they may find it rather hard going. There are words whose meaning they once knew but have probably forgotten; there is the vice (not unknown in their own field) of preferring the abstract word to the concrete; and there is an erudition which may give the ordinary medical reader an uncomfortable feeling of illiteracy. Nevertheless, he who persists will find the general conception original, the ideas stimulating, and the treatment of man's destiny essentially poetic.

Dr. Halmos holds that none of the scientific triumphs in the conquest of space has really changed the human sense of loneliness, or the longing for communion and "mystical participation" both with our fellows and with some suprahuman company of saints. His theme is that throughout history the growth of "culture" (the word is used to mean the standardising of social patterns and the mechanising of means of production) has resulted in a progressive "desocialisation" of the members of human communities. The more we are together, the less happy we seem to be. The pattern of the choral dance, evolved in prehistoric times, prevailed until the 18th century, and provided occasions for that merging of the one with the many, and for the experience of ecstatic states, which he believes to be not only a craving but a need. He contrasts with this the "taxi dance halls" of contemporary Chicago, where "there is little conversation, the patron may sit for hours besides others of his sex without conversing with them. The girls, likewise, stand for long periods without speaking. . . ." These halls epitomise the modern city, "in which the criteria of life are mobility, impersonality and anonymity." He makes the same sort of analysis of drinking habits. The consumption of alcoholic beverages cannot be traced over the same long period, but the evidence suggests (apart from a peak associated with the miseries of 19th-century urban life) a declining trend. Dr. Halmos holds with Belloc and Housman that "Beer does more than Milton can to justify God's ways to man," and that our modern tendency to substitute cola drinks, the cinema, and television is one more step towards imprisoning the human soul in its own ego. He also discusses ways in which modern psychiatric techniques break down some of the worst sorts of social isolation, and pleads for the use of "social psychotherapy" in group organisations of every sort. He is perhaps too optimistic in his hopes of what might be achieved by converting groups brought together for other purposes into therapeutic groups, but a note of optimism is not unwelcome in an otherwise gloomy picture.

This is an unusual book, something more than a careful well-documented scientific and statistical survey; indeed, it fulfils one of Mr. T. S. Eliot's requirements for literature, in that Dr. Halmos attends closely to the human heart as he knows it.

Practical Significance of Modern Cardiological Investigations

T. E. LOWE, F.R.C.P., divisional clinical research unit, Alfred Hospital, Melbourne; H. B. KAY, M.R.C.P.; H. A. LUKE, D.D.R. Melbourne: University Press. London: Cambridge University Press. 1951. Pp. 206. 45*s.*

THIS monograph suffers from the defects which might be expected of a prize essay put into book form. It is in three sections; one is devoted to the methods of cardiological diagnosis, and the other two to their practical application.

The first section gives a good description of the technique of modern diagnosis with a succinct account of the underlying principles and the possible errors in the use of the various instruments. It is not entirely confined to modern methods since palpation and auscultation find a place under the rather formidable disguise of vibrocardiography. The views are orthodox but the general reader will find the information useful and the explanation often illuminating. In the remaining sections the authors seem to have lost sight of their purpose or rather to have been overwhelmed by its magnitude.

The result is a miniature textbook of cardiology, which will not satisfy the specialist and will present others with a lot of tedious reading. The illustrations, though adequate in themselves, suffer from being compressed into consecutive pages without proper relation to the text.

Surgery and the Endocrine System

JAMES D. HARDY, M.D., F.A.C.S., assistant professor of surgery, University of Tennessee Medical College. Philadelphia and London: W. B. Saunders. 1952. Pp. 153. 25*s.*

THE title is ambiguous—and rightly so; for it embraces both the body's reaction to the stress of surgical trauma, and the surgery of the endocrine glands. In the first part Dr. Hardy shows himself to be a surgeon who is quite at home in endocrine physiology, and his account of the main features of the "alarm reaction" is an extremely good brief review of the subject. But his references to his own published and unpublished observations give the work a controversial flavour. Not all will accept his suggestion that the electrolyte depletion which commonly follows an operation may be more apparent than real (and is in any case part of a purposeful reaction to stress): though perhaps it will allay the alarm reaction of some of those over-conscientious house-surgeons who are for ever trying to restore the blood electrolytes to "normal." The second part describes the surgery of the endocrine glands on fairly conventional lines.

A Symposium on Essential Hypertension

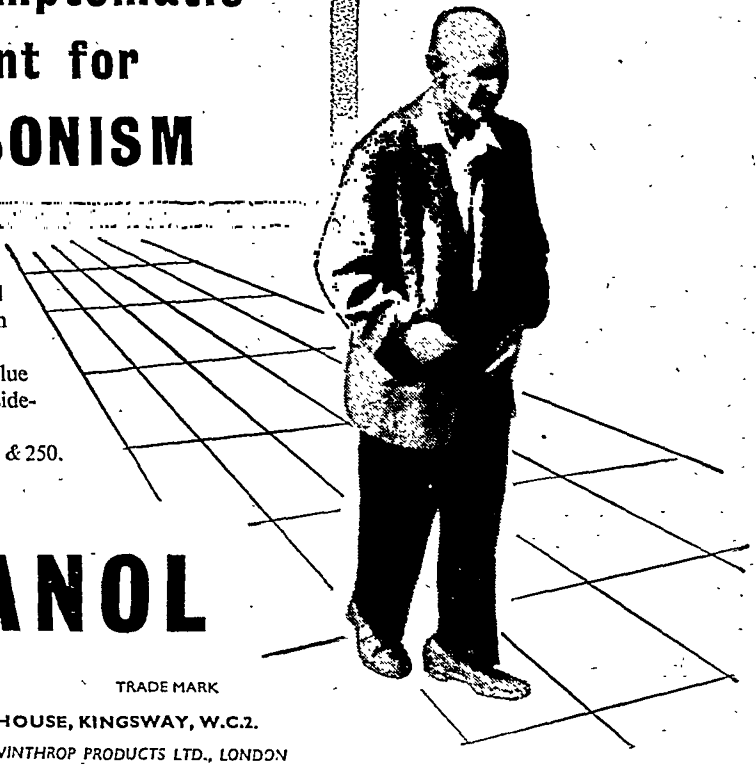
Sponsored by the Recess Commission on Hypertension. Secretary: VANCE L. ALDEN. Massachusetts: Commonwealth of Massachusetts. 1951. Pp. 373. $3.95.

IN 1950 the Court of Massachusetts decided they ought to determine what action, if any, should be taken by the State in the control and treatment of hypertension. To this end they appointed a commission, who convened a three-day discussion by experts not only in the clinical and laboratory fields, but in those of public health and social research. Symposia, followed by publication of the proceedings in full, have become a feature of American medical activity. There have been a number on hypertension, but this is the first with an epidemiological approach. Epidemiology is no longer confined to contagious disease, but covers the study of all factors and their interrelationships which influence the occurrence and distribution of any disease or disability. Accordingly the problem was defined—and difficulties were soon apparent.

A critical review of published work revealed the inadequacies of previous surveys, many of which have been based on life-insurance statistics. Apparently sampling of the population has rarely been statistically acceptable. There has been no agreement as to what constitutes hypertension and what allowance should be made for advancing age, nor even on how to take the blood-pressure. During the discussions hypertensive disease was defined and classified. Emphasis was laid on the importance of studying the prohypertensive state rather than patients who had developed symptoms, or in whom hypertension had been discovered on routine examination. It was suggested this might best be done by studying the children of hypertensive parents and following them through life. The case was stated for the neurogenic, psychogenic, renal, and endocrine hypotheses; and it was agreed that heredity was the only established ætiological factor. However, ætiology does not explain pathogenesis. Physiological investigations, pathological changes, and animal experiments were reviewed. The rôle of vaso-active substances, infection, injury, and pregnancy were discussed and attention then turned to social, economic, and physical environment and to constitutional and psychological factors. The adaptation syndrome was not forgotten.

If little new emerged, current knowledge was appraised and the problem classified. Gaps in knowledge were emphasised, and it was decided to make plans for a long-term community research. Not least in importance is the intention to publish a complete bibliography from 1920. No-one interested in hypertension could fail to derive pleasure and profit from reading this volume.

Effective symptomatic treatment for PARKINSONISM



Trihexyphenidyl, also known as benzhexol hydrochloride, is now manufactured in Britain under the name 'PIPANOL'.

Full-scale testing has indicated its value in all forms of Parkinsonism, while side-effects are negligible.

2 *mgm.* & 5 *mgm. tablets. Packings of* 100 & 250.

Please write for detailed literature

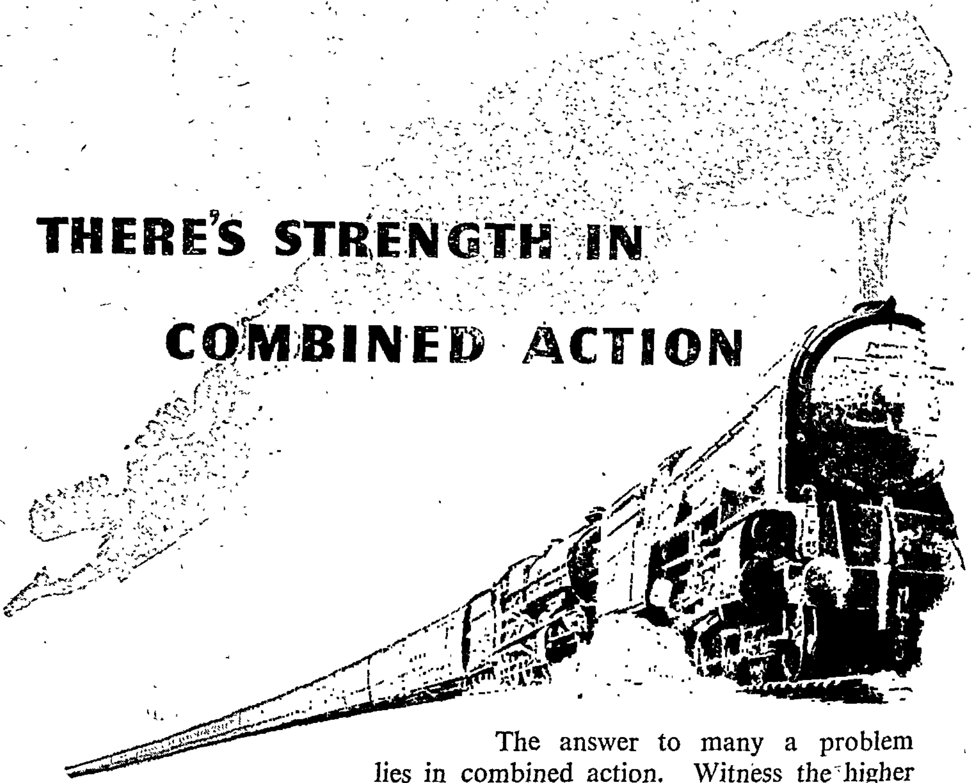
THERE'S STRENGTH IN COMBINED ACTION



The answer to many a problem lies in combined action. Witness the higher blood levels and the greater clinical efficacy that have been reported from the oral administration of penicillin and the sulphonamides simultaneously in cases when the oral administration of the antibiotic or chemotherapeutic agent alone has been ineffective. A convenient means of applying this combined antibacterial therapy is Sulpenin. Containing penicillin, sulphadiazine and sulphamerazine in balanced dosage, it provides a valuable treatment for many infections due to susceptible micro-organisms. By utilising the synergistic action between penicillin and the sulphonamides the antibacterial range is increased, the likelihood of kidney damage is lessened and the tendency for the bacteria to develop mutant strains resistant to one or other of the component drugs is reduced.

SULPENIN

Combined Oral Penicillin and Sulphonamide Therapy

New Ways with Tuberculosis

The symposium from Clare Hall Hospital which we print on another page shows how much the treatment of pulmonary tuberculosis has been changing. Ten years ago, as Dr. Norman Macdonald points out, artificial pneumothorax and thoracoplasty were the standard methods, with extrapleural pneumothorax just coming for trial. Chemotherapy had not arrived, resection was hardly risked, and pneumoperitoneum had scarcely found a footing. Now, with chemotherapy in full swing at the chest clinics, and resection a commonplace in chest units and sanatoria, the indications for the various types of collapse therapy are changing, and it seems diminishing somewhat. Thus at Clare Hall, Mr. Robert Laird notes, thoracoplasty is still much used in selected cases—mainly those with cavitation and fibrosis in the upper lobe. The number of lung resections, however, is steadily rising, this operation being often performed for large solid foci, large or tension-type cavities, and lower-lobe cavitation, as well as in cases where one lung is destroyed while the other is healthy or relatively healthy, in cases of permanent bronchial stricture with tuberculosis beyond it, in cases of empyema associated with gross lung disease, and in cases where collapse therapy has failed. There is still some overlap in the indications for thoracoplasty and resection. In Laird's series resection gave a sputum-conversion rate of over 90%, as against 70–80% for thoracoplasty; and since resection often leaves little deformity, it is likely to be less unpopular with patients. On the other hand it is still somewhat more risky than thoracoplasty: in the six months after operation the mortality among Laird's 580 patients treated by thoracoplasty was only 2·1%, as against a rate of 4·5% among 132 patients treated by resection. The dislike patients feel for a deforming operation has also encouraged the development of plombage, in which the chest is packed extrapleurally with some neutral substance, such as 'Lucite' balls, strips of 'Polythene,' or the 'Polystan' sponge described by Laird. It remains to be seen how the body will tolerate such foreign materials over the years; but the immediate results are good, and here again a two-stage operation is avoided.

The development of these new measures, as Macdonald reports, has been associated with a decline in the use of artificial pneumothorax, anyhow at Clare Hall. It seems extraordinary that we should not yet be certain when a pneumothorax can best be terminated, but, as he says, it has been employed on a large scale only during the past ten or twelve years, and we are only just beginning to see late results in any quantity. When refills cease, various hazards develop which the pneumothorax had held in check: in fact the patient's common plea—"I feel much safer with it, doctor"—seems to be thoroughly justified. After years of relative good health he may, when his pneumothorax is given up, become an invalid again or a candidate for major surgery. The difficulty, as Macdonald remarks, is to decide on the positive criteria for inducing a pneumothorax. There are plenty of negative ones. Too much toxicity, too much disease, too little disease, disease that is either too new or too old, a large tension cavity, a segmental lesion, a thick-walled cavity, emphysema, and tuberculous endobronchitis—all these discourage the physician from considering artificial pneumothorax, and it is seldom nowadays that he finds himself certain that in any given case it is exactly what the patient needs. Pneumoperitoneum, however, is still holding its own, both as a useful accessory to chemotherapy and as a temporary procedure to prepare a patient for operation. At Clare Hall, except in special cases, it has lost its old ally phrenic crush. A paralysed diaphragm may be very convenient at the outset of treatment, but later, if it fails to recover, or recovers incompletely, respiratory function is permanently limited; moreover, if thoracoplasty has to be done, a partially paralysed diaphragm may add to the chances of massive collapse. Pneumoperitoneum without phrenic crush, but with chemotherapy, has particular value, Macdonald finds, in pulmonary tuberculosis of hæmatogenous origin. The disease is commonly apical and symmetrical, leading to much fibrosis which pulls up the hila. Pneumoperitoneum relieves the emphysema in the lower zones by raising the diaphragm, and encourages the apical lesions to go on contracting. The trouble is that there is a risk of relapse if the diaphragm is allowed to descend; so pneumoperitoneum must be continued indefinitely. Moreover, though Macdonald does not mention this, pneumoperitoneum is liked less by patients than by physicians; few people care to acquire a permanent pot-belly, and single young women can find it seriously embarrassing.

The changing methods at the sanatoria are, of course, largely the outcome of the swift advance of chemotherapy, for streptomycin and *p*-aminosalicylic acid have already changed radically the type of case reaching the sanatoria. Another factor, as Dr. F. A. H. Simmonds reminds us, has been the growth and development of the tuberculosis service. It is not merely that (as he happily puts it) more surgeons have closed more cavities, but also that more early cases are being effectively treated by the clinics. Thus a higher proportion of those admitted to sanatoria for active treatment are sputum-negative: the figure, in fact, has risen from 28·5% in 1950 to 44–45% in 1951. We do not yet know, however, what proportion of patients who become sputum-negative while having rest and chemotherapy at home will be able to consolidate their recovery without further measures. Dr. Simmonds warns us that such sputum conversion may well be transient unless backed by collapse or other active treatment; and indeed he finds that the disease may be just as extensive, and the need for active treatment almost as great, in sputum-negative as in sputum-positive patients. This encourages speculation once more on what constitutes "tuberculosis." Recent experience with isoniazid[1] has shown that patients can feel and look well, and have no tubercle bacilli in their sputum, and yet show very little change in a serious X-ray picture. We do not know yet what course their structural damage will follow, though there is some evidence coming in of a delayed healing process, first apparent only some months after the clinical improvement. Some would say that, in the interval between the clinical and the structural change, we must regard the patient as a sick man still in need of treatment, while others might look on him as a well man in whom a process of resolution and scarring is at work.

---

[1] See *Lancet*, July 5, 1952, p. 19.

Whatever the ultimate picture may be, it is clear that chemotherapy has given us a big new advantage over the old adversary. Just as anæsthetics cleared the way for the surgeon by giving him time for careful and intricate work, so the new drugs have given chest physicians and surgeons time to consider the next move and develop new techniques—"room to manœuvre," as Macdonald puts it. Their influence on the rate of decline in mortality is already apparent in Simmonds's graph, though he warns us that the acceleration may not be maintained if the effect of the new drugs is merely to prolong life for a few years. But without undue optimism we may perhaps share his view that patients will in time separate into two groups: first, those with small lesions discovered early and for the most part treated successfully; and secondly, a diminishing group with incurable disease, who will need care for life.

Chlorophyll as Deodorant

One of the more bizarre items of recent news is the statement by Ritchie Calder [1] that the governor of a gaol in one of the Southern States of the U.S.A. does not allow his convicts to use chlorophyll preparations of any kind (even toothpaste) for fear that, if they escaped, the deodorant action of chlorophyll might prevent his bloodhounds from picking up the trail. Recommended to the public as a means of neutralising every form of unpleasant bodily odour, these preparations are sold in America on such a scale that the manufacturers are obliged to import substantial quantities of chlorophyll from this country, where it is prepared (largely from lucerne) as a by-product of the new grass-drying industry. In Britain, too, increasing sales show that the public is tentatively accepting the suggestion of certain advertisers that chlorophyll is a great help to social life in a small island.

Chlorophyll has the unique property of photosynthesis—building up sugars from water and the carbon dioxide of the air, and simultaneously releasing oxygen—and possibly this process is the key to its alleged deodorising action, which is more likely to be due to the oxidation than to the reduction of offensive gases and other substances. Though chlorophyll has not yet been completely synthesised, no doubt exists that its molecule is built up of a system of four pyrrol rings pivoted on a central magnesium atom. It is, in fact, closely similar to haem, in which the pyrrol rings similarly pivot on an iron atom. There is nothing to suggest that either of these molecules should possess any deodorant action; but this is merely another way of saying that the whole question of the connection between smell (positive or negative) and chemical structure is quite undeveloped. For the specific functions which chlorophyll and haem discharge with such incomparable efficiency in plant and animal life respectively, the *whole* molecule is indispensable. Any attempt to modify, by degradation or by synthesis, is immediately accompanied by a catastrophic reduction in catalytic efficiency. On the other hand, these molecules have, per se, a considerable stability not only to physical change but also to minor chemical modification, so that it is possible to effect substantial chemical reaction on them without the collapse of the pyrrol scaffolding. The central metallic atom may in either case be removed and replaced by another, or even by hydrogen. These modified structures retain many of the subsidiary characteristics of cholorophyll (or haem) and may be spoken of as chlorophylls, in much the same way as cholesterol and sex-hormone products are still "sterols." It will be seen that there is wide scope for marketing a variety of ill-defined mixtures of degradation products of chlorophyll; and if in fact the claims made on behalf of proprietary preparations of chlorophyll are justified there will be ample opportunity for the careful study of the potency and therapeutic indications of materials of known composition.

Westcott [2] claims to have shown that water-soluble chlorophyllin reduces the smell of benzyl mercaptan, thioglycollic acid, and trimethylamine. Dijkstra [3] has also reported in-vitro tests in which he incubated various foul-smelling materials—human pus, rotting cheese, and certain vitamin tablets—with a proprietary preparation of chlorophyll and found that the odours were abolished. On the assumption, then, that chlorophyll is a potent deodoriser, the most obvious way in which it might act is by inhibiting putrefactive bacteria. This possibility can readily be tested in the laboratory, and eight years ago L. W. Smith [4] and others worked on these lines. Smith concluded that "the ordinary pyogenic bacteria will neither grow nor survive for 24 hours in simple isotonic solutions of chlorophyll up to dilutions of 1 in 500," and he thought that an oxidation mechanism most easily explained the ability of chlorophyll to arrest anaerobic growth. Another relatively simple means of investigating the action of chlorophyll is to note the effects of applying it to infected wounds. Moss et al.[5] studied 36 patients and paid special attention to the rate of healing and to wound odour and appearance, and they concluded from their observations that chlorophyll is consistently an effective deodorant when used on foul-smelling wounds. They also said that the treatment improved the look of the wounds, giving them a healthy granulating appearance; but, though chlorophyll did not retard healing, there was no clear evidence that healing was accelerated. These results confirmed the earlier findings of Gruskin,[6] but not those of Bürgi [7] who claimed that water-soluble chlorophyllins stimulated epithelial growth and thus promoted healing of wounds and ulcers.

The reputed effect of chlorophyll as a general deodorant of body tissues and excretions is even more interesting and important, but it is also harder to understand. Many independent workers have now described investigations into the effects of chlorophyll on such odours as those often associated with sweating and with menstruation, and also the peculiar smells that sometimes emanate from the axillæ and the feet. Attempts have also been made to deodorise the breath or urine of people taking certain foodstuffs and beverages—garlic, asparagus, thiamine, and alcoholic drinks. There is an extraordinary measure of unanimity in claiming complete or almost complete success in these trials. Once again, however it must be emphasised that none of these workers has so far disclosed the exact nature of the chlorophyll preparation used: they mention merely the name of the proprietary brand. There seems to be an opportunity here for collaboration between an independent chemist and a clinical research-worker in an academic laboratory to provide a disinterested opinion on which of the chlorophyll products is responsible for these remarkable actions. If the action is simply that of an antibiotic, altering the bacterial flora of the intestinal tract, it is remarkable that the same effect does not seem to have been observed when streptomycin is given by mouth. Likewise, no remote deodorising action seems to have been noticed after administering succinylsulphathiazole as a preoperative measure to reduce the bacterial content of the colon. The alleged value of the chlorophyll preparations when given orally in cases of ozæna or of suppuration of bone adds to the evidence that the drug must be absorbed and exert its effects peripherally.

In a recent review on chlorophyll, Mitchell[8] refers to work by Calvin et al. which suggests that "pure chlorophyll *a* can act as an oxygen carrier, absorbing atmospheric oxygen and parting with it again when the absolute pressure is reduced to a low level." Mitchell also mentions observations made by his colleagues and himself which show that when the free acid chlorophyllin is exposed to air it is substantially altered—presumably by oxidation. He points out that when the sodium or potassium salt of chlorophyllin is given by mouth chlorophyllin is probably liberated by the gastric hydrochloric acid. It is suggested that after absorption and distribution to the various body tissues the chlorophyllin exerts its deodorising effect by acting as a mild reducing agent, itself being oxidised. Alternatively, Mitchell thinks, "it may catalyse oxidation of odorous material, perhaps by forming a loose combination with oxygen and parting with the latter at the sites of action." On the whole, he favours the hypothesis of mild oxidation rather than reduction and points out that this would be more likely to have a deodorising action on malodorous sulphur compounds. On the other hand, Kohler et al.[9] reported that chlorophyll is not absorbed from the gastro-intestinal tract. If this view is confirmed it will call for an entirely different approach to experiments on the fundamental pharmacology of chlorophyll in vivo. Meanwhile the statement provides some justification for the comment of the *Journal of the American Medical Association*[10]: "not only is the mechanism of action unexplained, but it is not at all certain that the action exists except in the mind of the observer." The *Journal* goes on to remark on the curious fact that not all herbivorous animals are entirely free from smell; and the same thought is expressed by R. W. Marsh in the following couplet which we take the liberty of reproducing from the *News Chronicle* of July 30:

> "The goat that reeks on yonder hill
> Has browsed all day on chlorophyll."

The biologist may point out that the characteristic smell of goats is confined to the male, but at least it proves that some smells are not abolished by chlorophyll in the diet. It would be interesting to know what other smells would appear if graminivorous animals were deprived of their chlorophyll.

Parahæmophilia

In 1947 Owren[11] reported the case of a woman with a hæmorrhagic diathesis who at first appeared to be suffering from lack of prothrombin in the blood, because Quick's one-stage prothrombin test gave a "prothrombin-time" considerably longer than normal. Owren, however, found that the prothrombin-time of this patient's plasma could be restored to normal by adding normal plasma from which all except traces of prothrombin had been removed. He therefore concluded that the patient was suffering from a deficiency of a hitherto unidentified factor, which he named "factor five"; and he called the condition "parahæmophilia" because of its clinical similarity to true hæmophilia. The deficiency seemed to be congenital in his case, but there was no family history.

Since 1947 it has become evident that Owren's factor V is probably identical with Quick's "labile factor" and with the "accelerator globulin" of Seegers and his co-workers. This factor acts by accelerating the conversion of prothrombin to thrombin in the presence of thromboplastin and calcium. This reaction, without the accelerator factor, proceeds only slowly, so that when the factor is absent the prothrombin-time—which measures the time prothrombin takes for conversion to thrombin in sufficient quantity to produce a clot—is considerably prolonged, even though adequate prothrombin is present. The accelerator factor is "labile" because it disappears gradually from stored citrated blood and after ten days none is detectable. Clinically these cases present with a hæmorrhagic syndrome that has been present for years. The usual investigations reveal a prolonged prothrombin-time (or apparently diminished prothrombin concentration), and this alone distinguishes them from true hæmophilia, in which the prothrombin-time is normal. Another, and convincing, distinguishing test is that the plasma from a case of parahæmophilia will restore to normal the clotting-time of the plasma of a known hæmophilic patient; conversely hæmophilic plasma, which does not lack the accelerator factor, will restore to normal the prothrombin-time of plasma from a parahæmophilic patient. The true nature of a case of parahæmophilia can be found by showing that the plasma prothrombin-time can be shortened by adding normal plasma from which prothrombin has been removed, and the finding can be confirmed by showing that plasma from blood stored for more than ten days will *not* have this effect. By tests like these, several more cases have now been detected and reported.

[11] Owren, P. A. *Lancet*, 1947, i, 446.

In 1950 Frank et al.,[12] working in Turkey, reported the case of a man of 29 who came to their clinic with hæmaturia.

> This man presented the clinical picture of true hæmophilia; he had been known to be a "bleeder" since infancy and had, on that account, not been circumcised; he had had nose bleeding from the age of 2 and his first attack of hæmaturia when he was 3 years old; he had had no hæmarthroses and no purpura. A brother of the patient was said to have died in childhood from severe epistaxis. But further inquiry revealed that the patient's father had been affected; after circumcision the bleeding had been stopped only with difficulty and he had had severe epistaxes. Frank and his colleagues applied the usual blood tests to the patient and found that Quick's prothrombin-time was 47 sec. compared with the normal 11–13 sec.; and by further observation they found that when the prothrombin-time rose to 60–80 sec. the patient was liable to bleed. Transfusion of fresh blood or plasma reduced the prothrombin-time to 20–30 sec., and the effect lasted about 8 hours. They put this to practical use because, on this occasion, hæmaturia was found to be due to a stone in the kidney, and, by transfusing the patient with fresh blood 2 hours before, an operation for removal of the stone was successfully performed without undue hæmorrhage. Frank and his colleagues therefore considered that their patient had "parahæmophilia" and that in this case the defect was inherited.

Last year de Vries et al.,[13] in Israel, described a family that combined parahæmophilia with syndactilism. Of 7 siblings, 5 had syndactilism and a bleeding tendency, which de Vries et al. found was due to deficiency of prothrombin accelerator factor, and in 2 cases there was deficiency of prothrombin itself as well; both sexes were affected. The parents of this family were normal, and no other members were known to be affected. In the U.S.A., Stohlman et al.[14] recorded the case of a woman who had to receive a transfusion after severe postpartum hæmorrhage and who had a history of severe bleeding after tonsillectomy and a nasal operation. She also proved to have parahæmophilia, and they were able to show that the purified accelerator globulin provided by Seegers restored the clotting mechanism to normal. There was no family history in this case.

Lately Brink and Kingsley,[15] working in South Africa, have reported a hæmorrhagic syndrome among members of both sexes in more than one generation of a family; their investigations of 3 members showed that the condition was due to deficiency of the labile factor—i.e., parahæmophilia.

> Their first case was a woman of 27 who was in hospital for attacks of severe abdominal pain and menorrhagia. She had suffered all her life from hæmorrhages—epistaxes, bleeding after tooth extraction, and loss of blood from menorrhagia that had needed treatment with transfusions; nevertheless she had a daughter 8 years old, and the only complication of the labour had been a bloodstained vaginal discharge that persisted for 2 months. Her prothrombin-concentration, estimated by Quick's test, was 9–10% or even less. Brink and Kingsley showed that the deficiency was of prothrombin accelerator factor, and that transfusion of citrated plasma not more than 12 hours old restored the prothrombin-time to almost normal for about 8 hours. 1 sister and 1 brother had prolonged prothrombin-times, and the brother had serious spontaneous hæmorrhages from time to time. In this generation 3 other male siblings and 4 females were found to be normal; the parents were also normal. The family history showed that members of previous generations had had the same diathesis. The 8-year-old daughter of their patient had a slightly prolonged prothrombin-time, and so had the 2 daughters of the affected sister.

Deficiency of prothrombin accelerator factor can also, it seems, be acquired. Cosgriff and Leifer[16] have reported a hæmorrhagic syndrome apparently due to this deficiency in a man with cancer of the prostate and extensive bone metastases.

Parahæmophilia must therefore be regarded as a distinctive syndrome. It has justified its name. It resembles true hæmophilia in being a hæmorrhagic diathesis due to congenital or familial deficiency of one of the factors of the clotting mechanism, and it is liable therefore to be a life-long affliction. Unlike hæmophilia its inheritance is not sex-linked; Brink and Kingsley suggest that it is inherited through a recessive gene or a dominant gene with poor penetrance. It does not, like hæmophilia, appear to affect joints, but bleeding after tooth extraction or other operations and spontaneous bleeding from mucous membranes are typical features. In every case of hæmorrhagic diathesis the prothrombin-time should be estimated, usually by Quick's method or a modification. The discovery of a prolonged "prothrombin-time" in a patient with a congenital hæmorrhagic diathesis puts parahæmophilia into the differential diagnosis—and excludes true hæmophilia. Parahæmophilia can be distinguished from true hypoprothrombinæmia—which can also be congenital—by the tests mentioned above.

Treatment is simple. The bleeding can be controlled by a transfusion of fresh blood or plasma, preferably not more than 12 hours old. The resulting control, in the few cases reported, appears to be more successful than with true hæmophilia, and the case of Frank et al. suggests that major operations can be successfully performed. But, as with true hæmophilia, control lasts at best only a few hours, and it is not practicable to prevent hæmorrhagic episodes continuously.

Action of Antibiotics

Many years ago Ehrlich[17] recognised that the efficacy of a chemotherapeutic agent depends largely on the differences in its toxicity for parasite and host (Ehrlich's chemotherapeutic ratio). He showed that the affinity of a drug for an organism is closely related to its chemical structure and that its potency may sometimes be destroyed by changing a single atom—a specificity which he explained by his side-chain theory. At that time it was characteristic of all the compounds used in chemotherapy—the metals, phenols, and dyes, for instance—that though they had some selective action, mainly on the gram-positive bacteria, their power to kill micro-organisms varied with their concentration, and doses which were lethal to the invading organism were usually toxic to the patient. The notable fact about the first sulphonamide, 'Prontosil,'[18] was not so much that it inhibited bacterial growth as that it could be tolerated by the body in effective concentrations for a long time. Sulphonamides (like penicillin and streptomycin later) were used for several years before their action in interfering with the metabolic processes of micro-organisms was understood.

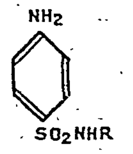
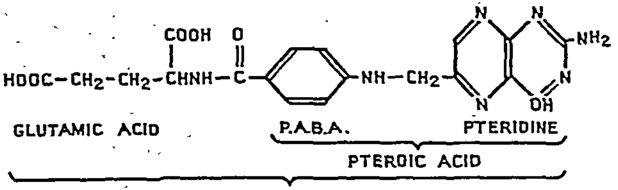
Sulphonamides were found to be inactive in the presence of pus and tissue extracts, and this observation led to Woods's[19] hypothesis that they inhibit bacterial growth by taking the place of *p*-aminobenzoic acid, which the organisms need for their metabolism and which the sulphonamides chemically resemble. This hypothesis led in turn to the remarkable work on biological antagonism between structurally related compounds.[20] The discovery of folic acid—a conjugated molecule of glutamic acid, *p*-aminobenzoic acid, and the base pteridine—which is essential for the growth of many bacteria, provided further confirmation.[21] It has been shown that micro-organisms which have no need of folic acid are resistant to sulphonamides, and so are those which must have ready-made folic acid as a growth factor.[22] On the other hand all those organisms which make their own folic acid from *p*-aminobenzoic acid are sulphonamide-sensitive. It is evident therefore that addition of *p*-aminobenzoic acid or folic acid should counteract the effect of sulphonamides on these bacteria. But as a matter of fact the exact rôle of folic acid in bacterial metabolism is not as simple as this picture indicates; for various compounds unrelated to folic acid—e.g., methionine, xanthine, and serine—have been found to oppose the action of sulphonamides, which suggests that several respiratory enzymes may be inhibited by sulphonamides. Further, folic acid seems to be concerned in the metabolism of nucleoproteins, especially with the reduction of desoxyribonucleic acid.[23]

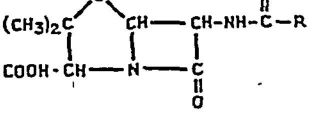


ULPHONAMIDES



FOLIC ACID (PTEROYLGLUTAMIC ACID)

Penicillin excels in its lack of toxicity, even when given in massive doses and over a long period. It has been possible to synthesise the penicillin molecule,[24] which consists of a curious ring-condensation of two amino-acids, β-dimethyl-cysteine and alanine, but the mould has not yet been surpassed in efficiency by the laboratory. The various penicillins are distinguished by the different acids coupled to the alanine. Penicillin is bacteriostatic in threshold concentration, but bactericidal in higher concentration,[25] and it has a preferential affinity for gram-positive organisms. Brilliant research[26] has shown that in their normal metabolism gram-positive organisms—in contrast to gram-negative ones—actively take up free glutamic acid and lysine from their environment. This process is accelerated by the magnesium ribonucleic acid which is present in the cell wall, and which is incidentally responsible for the gram-positive staining. Glutamic acid and lysine are concentrated in the interior of the cell, whence they are mobilised for protein synthesis. If penicillin is added to a *growing* culture of gram-positive organisms, it acts on the cell wall and disrupts the metabolism of the ribonucleic acid, thus preventing the normal assimilation of glutamic acid. Penicillin is, however, without any effect on non-growing cells. The sensitivity of the gram-positive organism and the immunity of the gram-negative one is explained by the fact that in the latter glutamic acid is synthesised inside the cell and does not have to be taken in from outside. Organisms which suddenly become penicillin-resistant assume accordingly some of the properties of gram-negative bacteria; they acquire the ability to synthesise glutamic acid and need not then assimilate it from their environment, so attaining an independence against which penicillin is powerless. These differences in the amino-acid metabolism of bacterium and host are the nutritional basis on which penicillin works.



PENICILLIN

Streptomycin is a glycoside containing streptidine, a base which is related to inositol (one of the B group of vitamins), streptobiose (which is a methylpentose), and glucosamine (which is a derivative of dextrose). The gram-negative and acid-fast organisms are particularly sensitive to it. Unlike the sulphonamides and penicillin, it affects not only growing organisms but those in the resting phase as well. Its bactericidal effect increases with higher concentration.[27] The action of streptomycin seems to be more complex and is less well understood than the action of sulphonamides and penicillin. It is known, however, that it interferes with the oxidation of threonine and serine in gram-negative organisms, as well as with the oxidation of fumarates and pyruvates.[28] [29] There takes place in the living cell a process called the "oxalacetate-pyruvate reaction"[30] which consists in the condensation of oxalacetate and pyruvate molecules, with the probable oxidation of many unknown intermediate compounds. This reaction is apparently as important to the animal as it is to the bacterium and it is inhibited by streptomycin. But why is streptomycin so lethal to certain organisms and relatively innocuous to human cells?

The enzymes involved in the oxalacetate-pyruvate reaction in animal tissues are mainly localised in the mitochondria, and streptomycin in relatively low concentration can only hold up the reaction if it is allowed to penetrate into the mitochondria. Streptomycin seems to concentrate largely in the extracellular fluids; little, if any, normally penetrates the cell itself. The explanation of its selective action seems to be that it is prevented from reaching the sensitive enzyme systems of the animal cell, presumably by permeability barriers at the cell wall and at the mitochondria,[31 32] whereas no such barriers exist in the bacterium. While penicillin and the sulphonamides upset anabolic reactions in the organism the strength of streptomycin is thought to lie in the blocking of a katabolic process—the oxidation of carbohydrates and amino-acids.

The effect of streptomycin on the acid-fast bacteria is even more complex. It has been impossible to demonstrate an oxalacetate-pyruvate reaction in the tubercle bacillus, but streptomycin has been shown to inhibit the oxidation of the higher fatty acids with twelve or more carbon atoms.[33] Very little is known about the metabolic pathways in acid-fast organisms, but everything discovered so far suggests a process comparable to the oxalacetate-pyruvate reaction.[31] In acid-fast organisms, therefore, the respiratory block seems to extend to the oxidation of fatty acids as well as carbohydrates and fats.

Organisms which have become resistant to streptomycin have apparently been able to dispense with the oxalacetate-pyruvate reaction or its equivalent in their metabolism. But there is another side to streptomycin resistance; Long[34] observes: "To begin with, although resistance to streptomycin may develop slowly, it can and frequently does occur precipitately by the production of mutants which are fast to streptomycin or, what is more astounding, by the emergence of mutants which need streptomycin as a growth factor!" Many pathogenic organisms, formerly susceptible to streptomycin, are now hardly affected by it, though fortunately *Mycobacterium tuberculosis* is seldom among the more resistant. As Long points out, it is this development which has led to the suggestion that streptomycin should be confined to the treatment of tuberculosis.

But not all the reported effects of streptomycin and the newer antibiotics can be attibuted directly to their action on bacteria and viruses. They can apparently produce remission in leukæmia, Hodgkin's disease, disseminated lupus erythematosus, and rheumatoid arthritis. Clearly our explanation is far from complete, and Dr. R. D. BARNARD discusses this perplexing aspect of the subject in a letter on p. 387 of this issue.

The interpretation of antibiotic action lagged many years behind its discovery and clinical application. It is interesting to look back upon the progress achieved and to see how much has sprung from a study of cell nutrition in man and bacterium. More potent drugs may be found as this work advances. Meanwhile we have yet to learn how the newer antibiotics such as chloramphenicol, aureomycin, terramycin, and isoniazid serve the purposes for which we thankfully use them.

Annotations

TWO TYPES OF MENTAL DEFECT?

IN 1914 Pearson and Jaederholm[1] made an interesting suggestion based on their careful survey of the mentally defective children, other than imbeciles and idiots, in Stockholm. They thought that most of the defectives with an intelligence quotient above 50 formed the lower end of the normal intelligence range, but the rest of these children, together with the imbeciles and idiots, were defective because of definite pathological changes. In 1929 Lewis[2] came to much the same conclusion after his investigation of mental deficiency in this country in connection with the work of the Wood Committee. He divided defectives into those who were essentially normal but "subcultural," and those who were "pathological." He suggested that the pathological group all possessed some definite lesion or abnormality, either responsible for or associated with their mental defect. Penrose,[3] however, in his very thorough survey in Colchester showed that many idiots and imbeciles, who were certainly in the pathological group, had no obvious physical lesions, and he suggested that other means must be found of distinguishing between the two types.

In the last few years Roberts[4] and his colleagues have made a special study in Bristol and Colchester of the brothers and sisters and the social background of 271 children in the range of intelligence quotient from 35 to 60—i.e., where the two groups might be expected to overlap. Their preliminary results, reported in the Galton lecture for 1952,[4] give considerable support to the hypothesis that there are two types of mental defect. They found that no well-defined division was possible on the basis of the children's own intelligence quotients alone, but that the children fell readily into two groups when the intelligence quotients of their siblings were also taken into account. With one group the intelligence quotients of the siblings were evenly scattered about a mean figure of 80; this is what one would expect if the children's intelligence was conditioned by many genetic and environmental factors, each having little effect in itself, and if the siblings had on the average half these factors in common with the original subjects of the experiment. In the second group the majority of siblings had intelligence quotients distributed in the same way as those of any random sample of the population, with a mean of about 100; but a few of them were severely defective. It was as if most of them had entirely escaped some single influence which had severely limited intellectual development in their brother or sister, but which had on isolated occasions affected more than one member of the same family.

Roberts's division of the children into two groups was admittedly subjective, but a later analysis of their social background gave further support to his view that the distinction was, in fact, a biological reality. The two groups of children were found to differ more in the social class and fertility of their parents than did groups distinguished only by the intelligence quotient of the one defective child. *Parents of the "normal"* group, as would be expected, were on the whole appreciably lower in the social scale and more fertile than the parents of the "pathological" group.

This separation of mental defectives into two distinct categories will, if substantiated, prove a useful guide

to further research, and suggest possible ways of making mental deficiency less common. The chances of reducing the number of "normal" defectives will be good, for the theoretical basis is there; improved social conditions, with the lower fertility-rate that they bring, seem to offer the best immediate hope. A considerable reduction in the numbers of "pathological" defectives can be achieved only when ways are found of detecting the carriers of the recessive genes for such conditions as phenylpyruvic amentia, amaurotic idiocy, and gargoylism, and when the unknown forces of environment which must be responsible for the bulk of gross mental defect are accurately defined.

CHLORAMPHENICOL AND THE BLOOD

IN the U.S.A. the Food and Drug Administration has announced its decision on chloramphenicol. The administration undertook a national survey to assess the danger of aplastic anæmia during treatment with chloramphenicol, disturbing reports of which have been accumulating in the past few months.[1] The decision is to permit the continued distribution of the drug in the U.S.A., but a warning note about the occasional occurrence of blood dyscrasias will be added to labels and to advertising circulars. Both notes will point out the importance of regular examination of the blood during intermittent or long-continued treatment, and the one on the circulars will warn doctors against using the drug indiscriminately or for minor infections.

In weighing the evidence, the administration examined the case-records of 410 patients who developed serious blood disorders; but only 177 of the disorders were definitely known to have been associated with the use of chloramphenicol. In 61 cases chloramphenicol was the only drug given, and in the remaining 116 other drugs had also been used. In these two groups together the mortality from conditions attributable to depression of the bone-marrow was 50%. This figure alone is alarming, but, according to the best estimates, chloramphenicol has been given to about eight million people since its introduction in the U.S.A., so the actual risk is small. It would have been regrettable if a drug of undoubted value had been condemned outright on such a slender chance. The responsibility of measuring the danger has been properly left in the hands of the prescribing doctor.

YAWNING

To most minds yawning is an infectious habit of the bored; but it may also arise from hunger, overeating, drowsiness, or bad ventilation; and it may come on with gastro-intestinal disturbances, after severe hæmorrhage, in association with hysteria, as an aura of epilepsy, and in encephalitis, Huntington's chorea, and cerebellar abscess or tumour. The yawn may not be restricted to man: Crämer[2] suggested that the gaping of fishes, amphibians, and reptiles was closely analagous; and the gaping hen beating its wings on tiptoe is an everyday sight to the poultry-keeper.

Mayer[3] found that during the first part of the inspiratory phase there is expansion of the chest with descent of the diaphragm and larynx, elevation of the alæ nasi and soft palate, downward and backward displacement of the tongue, abduction of the vocal cords, and opening of the mouth. This is immediately followed by closing of the eyes and stretching, notably of the muscles of the neck and upper limbs. Mayer described yawning as an automatic expression of cerebral fatigue, in the sense that crying and laughing are expressions of sorrow and joy; while Hauptmann[4] suggested that it combated the loss of muscle-tone which results from enforced inactivity of the higher cerebral centres. Dumpert[5] suggested that it occurred when the cerebral circulation was unfavourably adjusted to maintain an alert state; he also held that it augmented the venous return to the heart, which in turn improved the arterial blood-supply to the tissues. Heusner[6] reviewed the evidence and showed that in the fingers and toes of normal adults yawning was followed by vasoconstriction, which was roughly proportional to the depth and duration of the inspiratory movement, and that it was attended by transient acceleration of the heart. These changes are similar to those recorded after deep inspiration.[7]

There is thus some reason for regarding the yawn as a mechanism for countering physiological aberration.

THE FORMATION OF ANEURYSMS

THE progress of peripheral arterial surgery during the last quarter of a century has led to the development of technical procedures which give ever-increasing scope to investigation and treatment. Arteriography and plethysmography now give accurate knowledge of the site, extent, and character of lesions, and of the functional state of the circulation. Antibiotics, anticoagulants, improved methods of arterial suture, and the successful preservation of homografts have strengthened the surgeon's hand. Disobliterative operations and the restoration of continuity by grafting have now been added to arterial surgery, which was formerly limited to operations on the sympathetic system, and amputation when these failed.

Mr. S. M. Cohen, in his Hunterian lecture,[8] has reviewed the surgery of peripheral aneurysm and arteriovenous fistula in the light of these recent technical advances. His observations are based on experience gathered at a special vascular centre during the late war, together with material collected from other sources. Close observation of his cases has suggested to him some physiopathological ideas which will attract the attention of all surgeons who are engaged in this difficult but challenging work.

Leriche[9] has written: "Dans tous les anévrysmes, ce qui domine, c'est l'affaiblissement de la média et la disparition de l'élastique. Il faut étudier *les conditions de vie et de souffrance de l'élastique*." Cohen has followed this precept, and he finds, as did Halsted before him, that the stimulus which prompts the elastic tissue to meet the demands of local stress, and so control the calibre of the vessels, is the "rhythmical tensile stretch of systole—i.e., pulsation; and this is as essential for the well-being of elastic tissue, as the nucleus is to the cell." In this way he explains the phenomenon of "arterialisation" of the vein in arteriovenous fistula; here the vein thickens and resists ballooning under the unaccustomed arterial pressure, whereas in veins subjected to far lower pressures—as in portal hypertension, superficial varicosities, and deep-vein incompetence—enormous dilatation may be found. Similarly, when a vein graft is inserted to bridge an arterial gap, the graft holds. Yet "of all the layers, the elastic tissue alone survives. As the pulsating stream strikes the vessel wall, the elastic tissue responds, gathers strength, and holds without aneurysmal dilatation."

In contrast the artery, proximal and distal to an arteriovenous fistula, dilates and may become tortuous and greatly enlarged. These changes, Cohen suggests, "arise from weakening of the systolic stretch stimulus." The force of the pulse wave is dissipated in the fistula, and a mere "bobbing and curtseying of the vessel wall" results. Other effects of this loss of the stretch stimulus are the fusiform aneurysm of the subclavian artery sometimes seen in cases of cervical rib, and the dilatation of the aorta beyond a coarctation and of the pulmonary artery beyond a stenosis.

Cohen sees, in the varying hæmodynamic conditions resulting from arterial obstruction, changes in the pulsatile stretching of the collateral vessels, which is the appropriate stimulus to the elastic tissue in their walls, and which decides the development of their " tortuous and apparently ungodly jumble." This perhaps helps us to understand how it is that restoration of pulsatile blood-flow through the main artery, as occurs after disobliterative endarteriectomy, often results in lasting improvement in the circulation of the limb even though secondary thrombosis may lead to reobliteration of the main vessel.

Peripheral vascular surgery, having conquered most of the technical obstacles that delayed its early progress, now finds itself confronted by further difficult questions in physiology and pathology. These will only be answered by giving new thought, as Cohen has shrewdly done, to the whole subject of peripheral arterial injury and disease and the results of surgical intervention.

ANIMAL WELFARE LEGISLATION IN AMERICA

THE new Animal Welfare Institute (A.W.I.), lately founded in the United States, is experiencing the unpopularity usual among those who try to hold fairly to a middle course. In setting out its position,[1] however, it seems we have not adequately filled in the background. Dr. Herman E. Hilleboe, commissioner of health for the State of New York, writes :

> " The Hatch-Metcalf Act, which is now Section 5-a of the Public Health Law, does not ' make it a misdemeanour to harbor a stray animal without reporting it to a designated authority within twenty-four hours,', nor was such punitive action ever contemplated by the men who drafted the bill. The only penalties are those which are designed to discourage experiments upon animals without the approval of the State Commissioner of Health. The Act outlines the restrictions which are to be placed on the use of animals for experimental purposes and requires the Commissioner of Health to prescribe in detail and enforce the stipulated regulations.
>
> " I should like also to observe that this legislation which contains ' restrictions imposed from without ' was requested by research workers of the New York State Society for Medical Research who actively sponsored the law. The provisions of the law do indeed permit the requisitioning by the Commissioner of unlicensed, unwanted or unclaimed animals that are seized by municipalities or by legally designated private organizations. The bill also emphatically declares that no animal, licensed or unlicensed, may be requisitioned contrary to the wishes of the owner."

Certainly the Act makes no attempt to penalise those who harbour a stray animal without reporting it within 24 hours to the authorities ; and we regret having erroneously combined facts relating to New York legislation and that of Illinois, where a Bill as first proposed did contain this clause.

The animal protection clauses in the Hatch-Metcalf Act to which Dr. Hilleboe refers, are for the most part not new : they very largely restate an Act which has been on the statute-books of the State of New York for five years. But they contain the important new provision that violation of the law shall be a misdemeanour. The Commissioner of Health is authorised to approve laboratories and institutions where experiments on living animals may be conducted, and to prescribe the rules under which such approval will be granted. These rules will require that all such animals shall be kindly and humanely treated, properly fed and suitably housed, and that " commensurate with experimental needs and with the physiologic function under study " all experiments causing pain shall be done under adequate anæsthesia. The Act also provides that the State Commissioner or his duly authorised representative shall inspect the approved laboratories and institutions to ensure that the rules are being kept. Any failure to keep them may lead the Commissioner to revoke his approval ; and in any case approval will only be for a year at a time. A tentative " plan of operation," which Dr. Hilleboe has sent us suggests that laboratories and institutions will be inspected annually, but that those using cats and dogs will be inspected quarterly. It is clearly specified in the plan that animals should be given sufficient water and wholesome food, and kept in clean well-lighted and well-ventilated quarters maintained at a proper temperature ; and that quarters or cages should be large enough for the animal to sit, stand, lie, and turn round with ease.

The Act itself lays down that the rules shall be conspicuously posted in each laboratory and institution, so they may themselves serve an educational purpose ; but their influence, of course, will really turn on the character of the head of the laboratory. Approval is granted to the laboratory in his name and is not transferable ; and it is revoked if he ceases to be in charge. If he is humane, all should be well ; but it has to be borne in mind that some who have a genuine warmth for cats or dogs, or both, look on rats and mice much as they look on test-tubes. Responsibility ultimately lies with the State Commissioner of Health, but will be delegated by him to the division of laboratories and research, and to the district health officers, and sometimes to veterinarians, who will be the actual inspectors. In Great Britain, of course, the pattern is rather different, for responsibility lies with an authority entirely outside the health services—the Home Office—and the inspectors are highly qualified and carefully selected for their task.

The above provisions of the Hatch-Metcalf Act, if applied vigorously and sincerely, should serve their purpose well ; but there is still the question of the source of animals for experiment. Stray or unclaimed animals brought not only to municipal pounds, but to the pounds of private organisations, may be requisitioned for laboratory use—though, only, it seems from those private organisations which receive subsidies from municipal or State funds. This is the aspect of the Act which the A.W.I. found it impossible to support, since private animal welfare societies are formed to serve clearly defined purposes, and voluntary subscriptions are given to them on the understanding that they will be spent on those purposes. Some of the subscribers may disapprove entirely of animal experiment ; many others feel an objection—possibly sentimental, but easy enough to understand—to handing over an animal to those who may cause it pain, in however good a cause. True, the Act provides that licensed dogs surrendered to either private organisations or municipalities may not be requisitioned without the written consent of the owner ; and that other animals shall not be requisitioned if the owner so requests in writing. Moreover if a lost animal is requisitioned an extra three days' grace is allowed to give the owner a chance to claim it. Nevertheless the hard fact remains that private societies are compelled by the law to hand over animals whether or not they object in principle. It may be argued, of course, that they are at liberty to forgo their municipal subsidies and maintain their right of choice ; and it is true that most of our own humane societies would regard it as a bad principle to become dependent in any way on an agency, such as a State department, which had a vested interest in their affairs. But a private organisation which is financially committed—which, before this crisis arose, had accepted a municipal subsidy for building a pound, for instance—may not be free to choose independence. We still think the Hatch-Metcalf Act, good in so much, is marred by this arrangement.

THE GENERAL PRACTITIONER AND THE LABORATORY SERVICE [*]

M. N. S. DUNCAN
M.R.C.S.

GENERAL PRACTITIONER, PORTSMOUTH, HANTS

ALTHOUGH it has always been felt that in the National Health Service the general practitioner should have access to the laboratory, many hospital authorities remain reluctant to open their laboratories to him, fearing that to do so may lead to an overwhelming amount of largely unnecessary work. My object in this article is to show that access by general practitioners to a laboratory service would in fact save time and trouble alike for patient, general practitioner, and specialist. John Hunt,[1] describing the pathological investigations carried out in his practice during five years, makes the point that general practices differ enormously, and nowhere more than in the centre of a large city. He has found it satisfactory to employ a technician who is supervised by a consultant pathologist from time to time. In the area where I work, which is largely industrial, I have been able to refer my cases to a central laboratory where the advice of a consultant pathologist is available.

The practice to which I belong is carried on from a central surgery with three partners and part-time help from an assistant. Each of us gives all-round service. The practice is situated in the centre of a city of approximately 220,000 inhabitants, most of whom are N.H.S. patients.

THE PATIENTS

I have classified, from the point of view of pathological investigations, the patients I treated during nineteen months into the following seven groups. In the first group no laboratory investigations were required. In the remaining six groups was a total of 241 patients—about 8% of all patients who were attended over the period of nineteen months.

Group 1, in which diagnosis and treatment do not require help from the laboratory, contained over three-quarters of all patients. This may seem an abnormally high proportion, but it included the comparatively trivial, such as people with a common cold or a boil, and those who needed a certificate. In an epidemic there were many cases of, for example, influenza or the acute specific fevers of childhood, when only a minority of patients have severe complications presenting difficulties in diagnosis or treatment. Simple side-room tests or the use of some other simple therapeutic test often served to clinch the diagnosis. This group will tend to increase as doctors gain more experience in working with the laboratory, and my pathological colleagues have found that demands for many investigations tend to fall for this reason. For example, a general practitioner can easily carry out one of the simpler calculations for the estimation of hæmoglobin and need only refer for further investigation those which are found to be below an arbitrarily decided standard.

Group 2, in which the clinical diagnosis is fairly certain, but confirmation is desirable, contained a fair number of cases which, with increased experience, might easily be transferred to group 1. The investigations of urinary infections, renal function, or a possible pregnancy in an unmarried girl are all problems with which general practitioners are familiar. Though it is very desirable to establish the causal organism in say, a recurrent cystitis or pyelitis, I do not think it always necessary to do this in a patient infected for the first time who responds satisfactorily to expectant treatment. Renal function and pregnancy tests are difficult and specialised work, demanding the help of a skilled laboratory worker.

Group 3, where the clinical diagnosis is fairly adequate but confirmation is essential, contained cases where, without the aid of the laboratory, I could arrive at only a general diagnosis—e.g., "anæmia" or "glycosuria"—and more accuracy was needed for rational treatment. Many patients with diabetes mellitus, for example, can be adequately and safely treated by their own doctor (apart from pre-coma or coma), but before undertaking such treatment I regard a glucose-tolerance test as essential. Similarly, a patient with anæmia can easily be treated on scientific lines if skilled help is available for blood examinations. With this help, there will be no empirical use of liver, and no patient requiring liver will be treated only with iron. A pathologist who sees many thousands of blood films yearly may also, on occasion, suggest a test-meal, and a carcinoma of the stomach may thus perhaps be diagnosed before dyspeptic symptoms occur.

Group 4 contains the cases in which clinical diagnosis is quite insufficient. Pyrexias of undetermined origin are probably the commonest conditions of this kind that we general practitioners see, but there are many others which often turn out to be very interesting and instructive—the patient who may be an early Addison's disease, the case of hepatic or renal failure, the differential diagnosis between an anxiety state and a masked thyrotoxicosis, the case of fever with intense headache and no respiratory symptoms which turns out to be a virus pneumonia. In this group the general practitioner and the consultant pathologist, working together, may save the hospital beds and the hospital staff many hours of work. I have gained the most instructive experience when I was able to remain in direct charge of these patients, and when a consultant clinician was called in he was presented with a case in which a serious effort had been made to arrive at a diagnosis and there was every need for his special skill and experience.

Group 5, where the presence of active disease is in doubt, comprised the patients whose treatment I found it difficult to decide. Was it justifiable to treat this patient on expectant lines; or should I refer him to an outpatient department, which might waste a great deal of everybody's time? By asking for a simple erythrocyte-sedimentation rate (E.S.R.) or plasma-viscosity measurement, I could often solve the problem. A not uncommon example of this group is subacute rheumatism in children where in the absence of such help, the vagueness of the symptoms and the slightness of the signs might well have led me to postpone any action until the disease had become well established. Another example is possible early pulmonary tuberculosis. Despite the excellent work of the chest clinics, mass-radiography units, and school doctors, we are still often the first doctors to see such cases, and our task will be made easier if we have access to the laboratory for sputum and other tests.

Group 6, the therapeutic control group, contained patients who were receiving, for example, thiouracil, 'Tridione' (troxidone), or liver. All those under my care who are receiving the two former have a total white and granular cell count weekly. As a result, in one of my patients with thyrotoxicosis a steady diminution in the granular-cell count was noticed in good time, and the dose of thiouracil was adjusted with a consequent rise in the granular-cell count. This treatment still causes agranulocytosis, which is occasionally fatal,[2,3] and the precaution of a weekly white-cell count is essential on both clinical and medicolegal grounds. The same is true when troxidone is given for petit mal, while the necessity for periodical blood examinations of patients under treatment for pernicious anæmia is generally accepted.

Group 7 are the maternity cases. If the general practitioner is to undertake antenatal care and conduct domiciliary or nursing-home confinements, he should be able to offer as good a service as an antenatal clinic. He cannot do this unless he can obtain the routine blood-tests regarded as essential by all who practise obstetrics. The general-practitioner obstetrician has the great advantage of knowing his patients and their background well, but unless he can also offer up-to-date scientific safeguards to any pregnant woman who places herself under his care he cannot do his job properly.

THE INVESTIGATIONS

I also kept records of the investigations I requested from the central laboratory for these patients during the same nineteen months. Below is an analysis of my requests.

Investigations	798
Patients	241 (approx. 8% of all patients seen)
Domiciliary visits by the pathologist..	45
Patients attended the laboratory ..	226
Investigations per patient	3·3

Hæmatological (*496*)

Red cells	31	Mean cell diameter ..	10
Hæmoglobin	122	Mean cell hæmoglobin content	8
White cells	121	Packed-cell volume ..	40
E.S.R. and plasma viscosity	71	Platelet-count	5
Blood-group	42	Bleeding-time	2
Rhesus factor	42	Clotting-time	2

Bacteriological (*99*)

Sputum	15	[illegible] ..	2
Throat swabs	16	[illegible] ..	2
Vaginal swabs	4	[illegible] ..	2
Wassermann reaction ..	41	Blood-culture	6
Gonococcal flocculation..	3	Fæcal culture	5
Paul-Bunnell	3		

Biochemical (*102*)

Basal metabolic rate ..	16	Fæcal fats..	1
Blood-cholesterol ..	17	Blood-urea	17
Fractional test-meal ..	8	Urea-clearance	3
Glucose tolerance ..	5	Microscopical examination of centrifuged deposits in urine ..	15
Plasma-protein	18		
Serum-iron	2		

Other investigations (*101*)

Hogben pregnancy test ..	54
Others	47

DISCUSSION

The high number of hæmatological tests is due to investigation of anæmias, pyrexias of undetermined origin, routine antenatal examinations, and therapeutic controls. As I gained experience, I asked for more packed-cell-volume estimations and fewer red-cell counts and colour indices. One of the advantages of liaison with the laboratory is that they are able to advise on the way in which the desired information can be obtained with most economy of time. Likewise, plasma-viscosity measurements were increased at the expense of the E.S.R., for I found them more accurate. The high number of Hogben tests was due in part to a particular problem in this city, which is a naval port. Many Service wives (for reasons connected with postponing the overseas postings of their husbands) wish to have unequivocal evidence of their pregnancy as early as possible. At one time also those seeking admission to hospital for their confinement had to apply at the second month, and they were unwilling to do so unless sure of their pregnancy. A few are accounted for by my custom of always asking for this test on unmarried girls who suspect they may be pregnant. Under the heading "other" tests I have included those which have been carried out by the laboratory staff in amplification of those I have requested.

CONCLUSIONS

The result of having access to the laboratory service has been that, with the help of the consultant pathologists, with whom I discussed any difficult case, I have been able to deal with many patients whom I would otherwise have had to send into hospital or, at least, refer to an outpatient department. Before seeking a consultant clinician's advice I have been sure that every effort has been made to solve the problem.

Many, if not all, of these patients would have had the same investigations, and perhaps more, requested for them in the wards and outpatient departments, for newly qualified house-officers sometimes ask for more investigations than are really necessary. I have myself found that increased experience of general practice, in close liaison with the laboratory, tends to prevent a continual rise in the number of investigations, and in some instances it has led to a fall.[4] Any increase in the investigations carried out by the laboratory due to general practitioners having access to their services is probably only apparent.

I am convinced that everyone will benefit from opening the laboratory to the general practitioner. Specialists will not have their outpatient departments crowded with comparatively simple cases who need no more than a few routine investigations, nor their time wasted in domiciliary visits to similar cases. Pathologists will be drawn more into the stream of medical practice in the town, seeing the patients themselves, and discussing them with their clinical colleagues. Patients will be safely treated at home far more often, and will avoid the domestic upset caused when the housewife and mother is admitted to hospital, and the emotional upset to a small child separated from his mother when he is ill.[5] The family doctor will be given an opportunity for closer coöperation with other doctors and a greater incentive to keep up to date. Access to the laboratory may also help him to regain, where he has lost it, his position as the trusted adviser to his patients on scientific medicine, as he is on so many of the other problems which they bring to him.

SUMMARY

1. The pathological investigations requested by one partner in a large general practice over nineteen months are analysed.

2. The effect of giving the general practitioner access to a laboratory service is a reduction in the demand on hospital bed space and outpatient sessions.

3. Such access does not necessarily mean an increase in the total demand on the laboratory. If the patient had been sent to the hospital outpatients or ward, the same investigations would probably be requested.

I should like to thank the pathology staff in this area, for their unfailing help in the problems of general practice, and also for their help in the preparation of this paper.

BOOKS ON HOSPITALS

FROM A CORRESPONDENT

COMPARATIVELY few books dealing solely with hospitals have been published in this country. More have appeared on the other side of the Atlantic, but not many of them are really useful to the newcomer to hospital work. The professional administrator will now have his treasured copy of the fourth edition of Captain J. E. Stone's encyclopædic *Hospital Organisation and Management.* He may too sometimes refer to MacEachern's similar volume from Chicago, which bears the same title. There are, of course, useful technical books like Mr. S. R. Speller's *Hospital Law* and several concerned with building and construction, but of those I shall not speak here.

THE LAST HUNDRED YEARS

Florence Nightingale's *Notes on Hospitals* came out in 1859, and there were later editions; copies are still easily obtainable through the second-hand booksellers. Anyone who takes hospital work seriously should not fail sometime or other to handle this old classic. It starts with notes on the sanitary conditions of hospitals, and goes on to deal with defects of hospital plans, principles of hospital construction, and Indian military hospitals. It has an appendix on five different systems of hospital nursing—Miss Nightingale's first analysis, which shows how she approached the subject. Much of the book is obsolete: times have changed—"don't bring the sick out of fresh air into foul, as in a town hospital." It should be read now, not for guidance as to what we should do today, but to see *why* our hospitals are what they are.

---

[4] Peterson, O. L. Study of the National Health Service of Great Britain. London, 1952; see *Lancet*, 1952, i, 910.

[5] Bowlby, J. W.H.O. Monograph Series, no. 2. Geneva, 1951; p. 146.

What for example do we think about the size of wards? "Taking sanitary and administrative reasons together thirty two patients is a good ward unit." Or we discuss curtaining in wards: "In most French hospitals, and in some in this country, the beds have curtains. They are not necessary. They interrupt the ventilation and entail additional cost in washing: a low movable screen is preferable." *Notes on Nursing* is another classic; and so is E. T. Cook's two-volume *Life of Florence Nightingale*. Mrs. Woodham Smith's recent biography has had the benefit of access to much personal material denied to Cook, and some will prefer it to the older book. Both are excellent, but Cook has had too long an innings among the discerning to be easily displaced.

Florence Nightingale was followed by Sir Henry Burdett, editor of the *Hospital* and of his formerly popular *Hospital Annual*. In 1893 he brought out four volumes entitled *Hospitals and Asylums of the World*. The first of these volumes made an attempt to survey hospital history; but this was somewhat patchy and failed to take account of a good deal of information one would have supposed readily accessible to him. He ranged about the world and published plans from all quarters of a world which for more than a generation had been busy building hospitals with great enthusiasm. Copies of Burdett's four volumes are not easy to come by, but as a substitute any old volume of his *Annual* will help the reader to recapture the atmosphere of hospital work of that time. But perhaps only those with a liking for his rather bombastic Victorian style will find Burdett worth while.

Sir John Simon's *English Sanitary Institutions* was produced in 1890. Describing as it does at first hand the spate of public-health legislation of the late 19th century, its vigorous language helps to remind us of the astounding story. But it hardly mentions the hospitals.

Apart from the works I began by mentioning, almost nothing has appeared in Great Britain in the last half-century strictly on hospitals as such. There are one or two popular or semi-popular books: Redmond-Howard and Evans wrote in half-historical, half-descriptive vein in 1928 on the *Romance of the Voluntary Hospitals* in the latter heyday of voluntary sentiment, and recently Mr. A. J. Wise has edited a volume entitled *Your Hospital* which offers a sketch of the kind indicated by its title. But of serious stuff for interested laymen there is nothing but P.E.P. reports and white-papers. A very brief sketch from the historical angle by A. G. L. Ives entitled *British Hospitals* was included in Collins's Britain in Pictures series in 1948. An outline account of the history of the last fifty years by Mr. J. F. Milne, which may serve as a peg on which to hang the various reports, appeared in the *Hospital* for January, 1951. The student will look out the Cave Committee report of 1921, and, more to the point, the Dawson report of 1920 which has recently been reprinted by King Edward's Hospital Fund for London as a text indispensable to a course of thinking on hospital topics: we have not yet seen the last of the ideas which this farsighted report first put into words. There are sections too of a report by the Liverpool Hospitals Commission of 1935 which gave an unrivalled description of the working of the voluntary hospital system between the wars.

HOSPITAL HISTORIES

The gap in the picture must therefore be filled in from other sources, among which the histories of individual hospitals are important. In the forefront in point of interest is Sir Ernest Morris's *London Hospital*, first put together in 1910. It has an appendix on Modern Administration, which offers many quaint contrasts with hospital affairs today. Florence Nightingale was nearly out of date about wounds: "wounds heal in towns just as well as anywhere else, in the majority of cases," thought Morris. In the outpatient department "men are always seen first in order that they may get back to work. Women afterwards." Despite archaic touches like this, as well as an almost unbounded and uncritical enthusiasm for the voluntary system, and despite too a certain Edwardian sentimentality, the book is full of good sense and ought to be widely read again today. "I never go round the hospital at night but I picture the shades of the great dead walking the long corridors and down the great wards." Morris was probably the best hospital administrator of his generation. He died in 1937.

St. Thomas's and the Middlesex have brought out excellent short illustrated histories recently, and Guy's a commemorative volume on a similar scale. There are longer histories of the two ancient foundations, *St. Bartholomew's* by Sir Norman Moore (1918) and *St. Thomas's* by Prof. F. G. Parsons (1932–36) in two and three volumes respectively: both quote extensively from old documents and minute-books and make one wonder whether nursing was so uniformly incompetent in the immediate pre-Nightingale era as one is often led to suppose. There are a good many other histories. That of Worcester by Dr. W. H. McMenemey, published in 1947, is one of the most generally interesting. The latest of all is *Portrait of a Hospital* by Dr. William Brockbank published this summer on the occasion of the bicentenary of the Manchester Royal Infirmary.

PAST TO PRESENT

Cushing's *Life of Sir William Osler* helps too to bridge the period of hospital affairs from the Nightingale epoch to the 1920s, and conveniently brings America into the picture. It is now reissued in one volume, much too heavy for comfortable handling. It is a book which should be read casually by the fireside; if the author's commentary is sometimes tedious, the many quotations from Osler himself are never dull and often throw light on aspects of hospital affairs which otherwise escape the lay administrator. His *Evolution of Modern Medicine*, though not very modern, provides the layman with an easy introduction to medical history. More solid general histories of medicine are of course Prof. Charles Singer's *Short History of Medicine* and Dr. Thomas Guthrie's more recent illustrated volume. There is too the *British Medical Journal*'s stimulating compilation *The Last Fifty Years*. For a very brief but excellent sketch made vivid with portraits in colour there is McNair Wilson's volume in the Britain in Pictures series. Reverting to Osler, one must not forget to glance at, if not to seek out, a copy of *Æquanimitas*, a book of talks and addresses on hospital topics, sometimes found on the shelves of wise hospital matrons and others who need ideas for talks to nurses.

Dr. S. S. Goldwater's book *On Hospitals* is one of the relatively few books from the other side of the Atlantic which is sufficiently general to be useful to the hospital world here. It is a reprint of essays and articles which reflect the mentality of the man who was probably America's foremost hospital administrator of the last generation. He was a great advocate of training for the hospital administrator, and he pitched his standards high: "to carry out the policy of the average board of trustees is not enough." Another of the recent books from the other side which is well worth attention has the unpromising title of *The Hospital in Contemporary Society*; it hails from Harvard medical men at the Massachusetts General, in Boston, and contains what is all too rare in hospital literature, a few thoughts on the philosophy behind hospital provision. The first historical essay of some 70 pages by Dr. Edward Churchill is one of the best short accounts of the history of hospitals. There is a searching, questioning note running through it that is a refreshing contrast to the complacency which marks too much of the American hospital literature. Simon Flexner's reports to the Rockefeller Foundation on Medical Schools may seem remote from British hospital affairs in 1951, but to open one of his books is to observe a strong mind at work, and it is salutary to be reminded of fundamentals.

NURSING

There is very little about hospital nursing that the layman will find worth while. Miss McManus's book, *Hospital Administration for Women*, was first published in 1934, and despite revision it does not quite reflect the thought of today on hospital affairs as seen from the matron's office. Mrs. L. R. Seymer's history of nursing is the best of its kind and includes a useful section summarising the characteristics of the four main systems of nursing—the Nightingale, the American, the Motherhouse, and the Continental. But it is open to the criticism that it does not discuss difficulties: no reader would imagine, for example, that the legislation of 1919 could be regarded as seriously mistaken. Both these books are, in parts, liable to harden the attitude of the nurses of tomorrow on matters where an open mind would offer better hope of happy hospitals. Another history is the *Story of the Growth of Nursing* by Miss Agnes E. Pavey.

BACKGROUND READING

Ranging further afield, one may ask how else should the general reader try to fill in his background? If he only wants to appear knowledgeable at the house committee he may have secret recourse to the King's Fund Visitors' Manual (1950) which will suggest questions that can fairly be asked without delving too deeply into financial or other complications. But if he really wants to understand the principles of hospital administration as understood in 1952 in the light of all that has gone before, he will have to pick out something here and something there from a not very extensive literature such as I have tried to indicate above. He may try to leaven it with a reading of one of the modern guides to management in business, such as Urwick's *Elements of Administration*; but this, though useful, will not take him very far, and it is hard to find a really satisfactory peg which will keep in their proper place the different hints which may be drawn from the field of industrial management. If he wants to understand how nearly the hospitals were transferred to the county and county-borough councils in 1946, and just why in the end that solution was rejected, he will have to know something of the history of the county councils, from their creation in 1888 through their heyday during the first third or so of the century. For this he might look at the *Life of Sir Robert Morant* by Bernard M. Allen; and Beatrice Webb's short and readable autobiography will help too to throw light on the period. He will need to understand the complications of the white-paper of 1944, which Mr. Bevan so promptly rejected when the Labour Government came into power. Whilst reading all this he will have to try to carry in his mind the strength and the sentiment behind the old voluntary tradition, with which the county councils had found themselves in uneasy partnership since 1930, and the revealing light thrown upon the scene by the war-time experience and the Ministry's hospital surveys of 1942–45. Prof. Richard Titmuss in his *Problems of Social Policy* touches on this period, but his approach will seem somewhat cold and unsympathetic to the difficulties of many of those who were actively engaged in keeping the hospital system going. It does, however, help to explain the position as seen from Whitehall and the difficulties of reconciling the old independence of the voluntary hospitals with the central control inseparable from war-time, and in any case needed to meet changing social conditions.

There is a conspicuous lack of material dealing in non-technical terms with the medical staffing of the hospitals. Few people outside the medical profession—and not all within it—appreciate the importance of the medical committee in the evolution of the hospitals. It is not merely important, it is an integral part of the structure of all hospitals where consultant work is taken seriously. Now, in the last few years, a revolutionary change has occurred in the staffing of the hospitals. Instead of having groups of consultants here and there to whom general practitioners can refer their cases, we have decided officially to have consultant staffs in *all* hospitals. Nowhere is this epoch-making change described or discussed, except incidentally in the surveys—before the recent changes had really been thought out—and, to some extent, in the Ministry's illuminating guide entitled The Development of Specialist Services (R.H.B.[48]1). But there the emphasis is on the various specialties rather than on the administrative implications. Yet every regional board and every hospital management committee has had to discuss these matters and worry its way through towards a working solution.

Hospital administration raises many interesting and really important questions, and the principles involved are only now beginning to be discussed with the attention that they deserve. I have previously attempted a brief sketch of some of the more fundamental principles under the title of Preface to Hospital Administration.[1]

CONTROL OF MEDICAL MAN-POWER

The Ministry of Health and the Department of Health for Scotland announce the appointment of a National Medical Manpower Committee to replace the Medical Priority Committee. The members of the new committee are:

Lord Haden Guest (chairman), Sir Russell Brain, Dr. E. A. Carmichael, Dr. H. R. Frederick, Dr. J. M. Gibson, Dr. D. F. Hutchinson, Dr. W. M. Knox, Dame Hilda Lloyd, Sir Sydney Smith, and Sir Cecil Wakeley.

The acting secretary is Mr. F. Bliss, Ministry of Health, Savile Row, London, W.1.

The committee has been appointed, in consultation with the medical profession, "to keep under constant review the best methods of utilising the available medical manpower and to make recommendations to the Government from time to time." It will carry on the task, hitherto performed by the Medical Priority Committee, of allocating doctors to the three fighting Services. It will be helped by advisers appointed by the Health, Labour, and Service departments.

Two central medical recruitment committees, one for England and Wales and one for Scotland, and a number of area recruitment committees dealing with the different branches of the service (general practitioner, hospital, and public health) in the different regions of the country, have been set up. The central committees, assisted by the area committees, will deal with the recruitment of young doctors to the Armed Forces for their national service. The committees, with the help of the Service and other departments concerned, will also screen doctors with reserve liabilities to determine their availability for service in the event of war.

The central medical recruitment committees are as follows:

England and Wales

Dr. E. R. Boland, Dr. J. B. Harman, and Dr. T. C. Hunt (appointed by the Royal College of Physicians); Mr. P. H. Mitchiner, Mr. J. B. Oldham, and Mr. Julian Taylor

---

[1] *Lancet*, 1950, ii, 450.

(Royal College of Surgeons); Mr. G. F. Gibberd and Mr. A. J. Wrigley (Royal College of Obstetricians and Gynæcologists); Dr. W. A. Low, Mr. M. H. Whiting, Mr. M. L. Formby, Prof. R. J. V. Pulvertaft, Dr. A. A. W. Petrie, Dr. M. H. Jupe, and Dr. G. L. M. McElligott (specialist associations in consultation with corresponding group committees of British Medical Association); Dr. G. F. Buchan (Society of M.Os.H.); Dr. A. Christian Wilson (Medical Women's Federation); Lord Webb-Johnson (Parliamentary Medical Committee); Dr. Janet Aitken, Dr. J. A. Brown, Mr. V. Zachary Cope, Major-General J. C. A. Dowse, Dr. R. O. Eades, Dr. R. M. Forrester, Dr. H. R. Frederick, Dr. A. W. Gardner, Dr. P. J. Gibbons, Dr. F. Gray, Lord Haden Guest, Dr. F. Hall, Dr. T. Rowland Hill, Dr. D. F. Hutchinson, Dr. J. A. L. Vaughan Jones, Dr. L. W. Jones, Dr. F. Lishman, Dr. I. M. MacAlister, Mr. C. F. Mayne, Dr. T. W. Morgan, Dr. J. D. R. Murray, Dr. C. E. Rusby, Dr. W. Rees Thomas, Dr. S. Wand, Dr. A. Weston, Dr. D. I. Williams, and Dr. W. Woolley (British Medical Association); Dr. A. Macrae, B.M.A. House, Tavistock Square, W.C.1 (secretary).

Scotland

Dr. W. M. Knox, Dr. I. D. Grant, Dr. W. Gibson, and Dr. C. J. Swanson (General Medical Services subcommittee); Dr. W. D. D. Small, Mr. W. Q. Wood, Mr. T. Murray Newton, and Dr. E. G. Oastler (Joint Committee for Consultants and Specialists); Dr. W. G. Clark and Dr. E. Neil Reid (Scottish branch of Society of M.Os.H.); Sir Sydney Smith (deans of medical faculties of universities); Mr. Thomas Hunter and Mr. W. S. Phillips (Scottish Executive Councils Association); Major-General E. A. Sutton (chairmen's committee of regional hospital boards); Lieut.-Colonel R. Hope Vere (Local Authority Associations); Dr. E. R. C. Walker, 7, Drumsheugh Gardens, Edinburgh, 3 (secretary).

Occasional Survey

BONE REGENERATION

Problems of bone growth and regeneration have interested surgeons and other experimenters for over 200 years. Their systematic study can be said to have been under way by 1739, when Duhamel[1] published his paper on the red staining of the bones of animals fed on madder. With the development of aseptic surgery the use of bone grafts became general, and a voluminous literature on the subject has accumulated during the past 70 years or so. Much of this, though forming a valuable record of advances in surgical technique, throws little light on the fundamental problems of bone growth and regeneration.

The Fate of the Bone Graft

The observation that a successful bone graft becomes incorporated in the skeleton, is fixed to and merges with the surrounding bone, and is found to be vascularised, naturally led to the conclusion that it had retained its vitality and produced the new bone which welded it to the surrounding bone of the graft bed.

REPAIR BY VASCULAR INVASION

The first person to produce good evidence against this interpretation of the naked-eye appearances was Barth,[2] [3] who in 1892–3 made careful histological studies of the sequence of events in the healing of bone grafts in animals. He used trephine discs from the skull and cortical grafts of long bones, and he worked mainly with dogs, replacing the graft immediately or within a few minutes in the site from which it had been removed. He concluded that in all bone grafts detached from their blood-supply the bone cells died and the tissue was incapable of growth. Repair was carried out by an active invasion of blood-vessels and connective-tissue cells from the surrounding tissue. This new tissue became attached to the surface of the graft and also rapidly invaded the available spaces and cavities in the graft, depositing new living bone on the surfaces of the dead bone, not only as layers on the outside but also as a lining to the cavities and spaces in the graft. Thus the graft became revascularised and welded to its surroundings.

Although there has been much controversy on the matter since Barth's time, and although some of his interpretations of the histological appearances cannot now be accepted, there can be no doubt as to the accuracy of his main conclusion that the bone cells of the graft die and disappear, and that the bone is therefore dead and can take no active part in the healing process. Dead bone, however, unlike necrotic soft tissue, is, if aseptic, accepted by the body, and can serve as a scaffolding on which new living bone is deposited. Although the bone cells are dead, the calcified bone matrix is very resistant to the action of enzymes, and it does not undergo autolysis. It may be absorbed—removed piecemeal by osteoclastic cells—by the same process which remodels living bone. If it is not absorbed, it often has new bone deposited on it, and is thus built into the skeleton where it can remain structurally intact for a long time. For example, detached bone fragments at the site of a fracture are found to be dead; some of them, however, often escape absorption and become incorporated in the bony callus where they can be identified, sometimes years later, as islands of dead bone, structurally intact but lacking osteocytes in the cell spaces.

From what is known of the transplantation of soft tissues, both normal and neoplastic, it is only to be expected that the cells of a bone graft will die. Tissues separated from their blood-supply can only survive if transplanted as small fragments in which the cells are in close contact with the host's tissues, where they can get sufficient oxygen and nutrients to keep them alive until they have been revascularised by the ingrowing capillaries of the host.

SOME EXPERIMENTS

Hancox[4] transplanted fragments (measuring about $2 \times 2 \times 0{\cdot}5$ mm.) of an embryo chick's skull into the chorio-allantois of developing chicks; they survived and became revascularised within 18 hours—apparently by junction of the host's capillaries with the cut ends of those in the graft.

Conditions are very different even in the smallest bone graft, and it is obvious histologically, both with larger grafts and with bone chips, that the bulk of the cells die. It has been argued that a few of the surface cells can survive and are responsible for, or at least play an important part in, the production of the new repair bone. It is, of course, impossible to exclude the survival of a few surface cells, and this is not unlikely with a fresh autogenous graft. But the number of surviving cells must be very small, and it seems improbable that they can make any significant contribution to the repair process. This question has been examined by Reynolds and Oliver.[5] Using a standardised technique with inlay grafts in the tibial cortex of dogs, they compared the results obtained with fresh autogenous grafts taken from the opposite tibia and with homogenous (dog bone) grafts. Some grafts were preserved in a 'Merthiolate'* bone bank; others were frozen at −20°C; and others boiled for ten minutes and then stored under sterile conditions. They confirmed Barth's observation that there is no evidence of cell survival in fresh autogenous grafts, all the osteogenic tissue being furnished from the surrounding bone. In the fresh grafts, however, the healing process was more rapid in its early stages; this was the result of a more rapid penetration of the graft by capillaries and osteogenic connective tissue from the surrounding bone. With the homogenous merthiolated or frozen grafts the penetration, though slower, was finally just as complete, and after ten weeks no difference between these and the fresh autogenous grafts could be detected. The boiled bone grafts were considerably more resistant to penetration by blood-vessels, and union proceeded much more slowly. This resistance of boiled bone to vascular penetration was also noted by Hancox.[4] It is clear, however, that in Reynolds and Oliver's experiments the reason for the resistance of boiled bone to vascular penetration was not the fact that it was dead, for the stored merthiolated bone which vascularised quite well was certainly dead when implanted. Some other factor must be responsible—possibly the coagulated and denatured state of the tissues in the Haversian canals and marrow spaces.

---

* 'Merthiolate' is sodium ethyl-mercurithiosalicylate. It was introduced about 20 years ago as an antiseptic and preservative for biological products. It has a relatively low cytotoxic action.

[1] Duhamel, H. L. *Mem. Acad. roy. des Sci.* 1739, 52, 1.
[2] Barth, A. *Arch. klin. Chir.* 1893, 46, 409.

It appears therefore that under standard conditions the rate of healing of a bone graft depends not on its content of viable cells but upon the ease with which the osteogenic tissues of the host can penetrate it and gain attachment to it. Drastic treatment such as boiling, which coagulates and denatures its organic constituents, makes it less susceptible to penetration and reconstruction by the host's cells.

The Origin of the Osteoblast

Another aspect of bone regeneration concerns the origin and specificity of osteoblastic cells. From what sources can the osteoblasts responsible for the bony union of a graft or fracture be derived? This problem has stimulated much experimental work and much controversy in the past. Some have thought that osteoblasts are specific cells which can only be produced by the periosteal or endosteal cells, others that any connective-tissue cells in the neighbourhood of bone may become osteoblastic under the stimulus of trauma and its sequelæ.

The study of cells of the connective-tissue group by tissue-culture methods was started by Maximow about 30 years ago. He and his successors have stressed the mutability of these cells, and the ease with which they can undergo structural and functional modifications.[7] It is now generally accepted that the reticulum cells of the bone-marrow have most of the potentialities of the embryonic mesenchyme, and can give rise, as occasion demands, to either the hæmopoietic group of cells or the collagen-forming types—fibroblasts and osteoblasts. Fibroblasts and osteoblasts are closely related structurally and functionally; they both produce a tissue composed of abundant collagen together with mucoid substances—mucopolysaccharides.

In bone repair, such as healing of a fracture or a bone graft, bone formation is always preceded by a proliferation of fibroblasts. The first sign of bone appears as an area of more closely packed collagen fibres, which gradually become partly obscured by the development of an amorphous refractile cement substance around them, giving rise to an island of coarse-fibred (non-lamellar) bone which rapidly calcifies. Before the development of cement substance all the cells have the appearance of fibroblasts, and there can be little doubt that here osteoblasts arise as a modification of fibroblasts. The conversion of fibroblasts to osteoblasts seems to take place easily enough in tissues close to bone, but much less often in connective tissues further away. However, small deposits of heterotopic bone are not uncommon on the edge of calcified foci—e.g., calcified tuberculous lesions in the lung, calcified arteries, and sometimes in laparotomy scars. Damage to muscle may also lead to bone formation (the so-called traumatic myositis ossificans).

Bone Formation by Induction

The exact nature of the stimulus which encourages fibroblasts to become osteoblastic is not known. It has been suggested that, in the region of a damaged bone, chemical agents diffusing out from injured bone or cartilage may "induce" fibroblasts to become osteogenic. (The term "induction" is used by experimental embryologists to describe the process by which one group of cells determines the direction of development of a neighbouring group. In some instances this effect has been shown to depend on the production of diffusible substances.)

INDUCTION BY TRANSPLANTS

Some of the most striking experiments demonstrating the production of bone by induction are those of Huggins,[8] who showed that, in the dog, bone was almost invariably formed in the fibrous tissue which surrounded an autogenic transplant of epithelium from the bladder, ureter, or renal pelvis. Such a transplant produces new epithelium which spreads out from its edge, and grows round to form an epithelial cyst. Huggins showed that the bone forms in the connective tissue near that part of the cyst wall formed by the newly proliferated epithelium, and not in the tissue near the surviving, but non-proliferating, epithelium of the transplant. Similar transplants of epithelium from gall bladder, stomach, jejunum, and prostate did not induce bone formation. The effect was produced on connective tissues of various fasciæ, on the capsule of the knee-joint, and on the connective tissue in muscle; it was not produced on the connective tissues of the kidney, liver, spleen, or wall of the bladder. Huggins found that the fluid in cysts developed from urinary-tract epithelium contained a higher proportion of calcium and phosphorus than the blood plasma—usually about 50% higher. He thought that the permeation of calcium and phosphorus through the cyst wall, particularly through the areas covered by thin newly formed epithelium, might be the stimulus which induced bone formation. Whatever may have been the nature of the stimulus, it is of interest that the tissues in which it acted—fasciæ, joint capsules, and the interstitial connective tissue of muscles—are also liable to undergo ossification in man.

INJECTION OF EXTRACTS

Levander,[9] following an observation on the development of new bone round transplants in the subcutaneous tissue and muscles of the rabbit, considered that substances inducing bone formation must diffuse from the transplant. He then made extracts of bone and fracture callus from the rabbit, and injected these into the thigh muscles of rabbits. Bone developed at 60 out of 70 sites of injection with alcoholic extracts; but 10 injections of watery extracts and 20 injections of alcoholic extracts of plain and striated muscle were negative.

Annersten [10] repeated this work on a larger scale, and obtained about 20% of positive results at over 200 sites of injection of various types of alcoholic extract of bone and cartilage. With alcoholic extracts of various tissues other than bone he obtained 2 positives in 43 experiments—one with tendon and the other with muscle extract. Another paper [11] from Levander's department reported positive results with alcoholic extracts of calf marrow, and twelve papers by other workers give results of similar experiments with alcoholic extracts of bone.[12 13] Six of these are confirmatory and six either negative or positive in control series with alcohol alone.

[11] Willstaedt, H., Levander, G., Hult, L. *Acta orthop. scand.* 1950, 19, 419.

Heinen et al.[13] obtained a higher percentage of positive results with alcohol alone than with alcoholic extracts of homogenous bone. They injected the material into triceps and quadriceps of rabbits, using Annersten's technique for preparing and injecting the bone extracts. They obtained 45% of positives with alcohol alone in a total of 77 injections, 29% with 24 injections of alcoholic extracts of bone, and 50% with 10 injections of alcoholic extracts of muscle. Their proportion of positive results with bone extract was about the same as that obtained by Annersten. It is difficult to understand the negative or very rare positive results which Levander, Annersten, and others obtained in their control series injected with alcohol alone or alcoholic extracts of tissues other than bone.

Certain types of muscle damage thus produce a connective-tissue reaction which is apt to result in bone formation. All those who have observed cartilage and bone formation in muscle after the injection of alcoholic extracts of bone, alcohol alone, or other types of irritant—e.g., calcium chloride—describe much the same sequence of histological changes. There is a central area of necrosis outside which lies a zone of vascular granulation tissue, showing a great proliferation of fibroblasts between muscle-fibres, some of which are necrotic and some calcified. Cartilage forms among the cells in the fibroblastic tissue, as isolated cells or as conglomerations of cartilage cells forming small nodules. A little coarse-fibred bone may form at this stage, but most of the bone is produced by secondary endochondral ossification in the cartilage nodules. (There is no evidence that the cartilage or bone formation is particularly related to the calcified muscle-fibres.[13])

NEW EVIDENCE

Although the existence of a specific osteogenic substance in extracts of skeletal tissue has not been proved, there is little doubt that pieces of dead bone or cartilage can in some way induce bone formation in adjacent connective tissues, even when these are remote from the skeleton. Urist and McLean[14] have brought forward further evidence on this question. They transplanted osseous and non-osseous tissues into the anterior chamber of the eye in rats. All the tissue used, with the exception of some epiphyseal cartilage, was autogenous. The fragments, introduced through a needle, were small enough to permit of cell survival. They found that the periosteum of normal mature rats did not produce bone, but the periosteum of young rats (aged three weeks) and that taken from the region of a three to four days old fracture in mature rats produced bone in about 50% of implants. Bone-marrow of mature rats also produced bone. Cancellous bone nearly always produced bone, but cortical bone, free of periosteum and marrow, rarely did so. It is of interest that the bone cells of even such small implants died and disappeared. Where new bone was formed, there was surface erosion by a vascular "mesenchyme" adjacent to the fragment; bone was then deposited on the eroded surface of the transplant, apparently by the vascular fibroblastic tissue ("mesenchyme") of the host, but bone formation by surviving surface cells of the implant could not be excluded.

Interesting results were obtained with cartilage, implants of which were made from epiphyseal and articular cartilage and from fibrocartilaginous callus. There was a high proportion of "takes" with all these cartilage implants, which were examined at intervals from six to thirty-six days after implantation, and the sequence of events was essentially the same with all of them. During the first week the implant became surrounded by an inflammatory granulation tissue forming a capsule round the graft. During the second week the capsule was divided into two layers by the formation of an inner layer of vascular mesenchyme; this produced absorption of the cartilage followed by a deposition of new bone on the remains of the cartilage matrix. This is exactly the same process as occurs in normal endochondral ossification, in the ossification of cartilaginous fracture callus, and in the ossification of cartilaginous nodules in muscle. The point of interest here is that the invading tissue which produces the cartilage absorption and deposits the new bone is, or appears to be, furnished by the tissues of the host.

Urist and McLean then showed that the same result can be produced by induction. They implanted fragments of fibrocartilaginous fracture callus, killed by boiling in saline for three minutes (and also by freezing, but boiling is the more certain guarantee of death), and they found that the dead implant was absorbed by a similar vascular tissue (here unquestionably derived from the host) which also deposits bone on the surfaces of the partly absorbed cartilage. This process differed from what happened with the living implant only in the production of a much thicker fibrous capsule, and in the slower development of the cellular reaction leading to cartilage absorption and bone deposition.

It has usually been assumed that the production of bone by induction is dependent on soluble substances diffusing from the inducing tissue; experimental embryologists have, however, shown that in some tissues direct contact between the cells of the inducing and the induced tissue is necessary.[15] This may be the case when implants of bone or cartilage are the inducing agents. On the other hand, since erosion of the surface of the implant by the action of osteoclasts or similar cells commonly precedes bone formation, soluble products, both organic and inorganic, must be liberated from the transplant. So far, however, no specific inducing substances have been identified.

Medicine and the Law

Defamation Proceedings

THE Ministry of Health has assured the British Medical Association that, in the event of proceedings for defamation against a doctor arising out of his entries on a hospital patient's case-papers by reason of their loan to, and use by, the Ministry of Pensions or the Ministry of National Insurance, the Minister will indemnify the doctor against any damages that may be recovered and against all reasonable costs that he may incur in defending the proceedings. The indemnification of medical practitioners called on to disclose confidential information before tribunals is also covered by this assurance.

If legal proceedings seem likely to arise it is advisable for the doctor to consult his defence society in the first instance, since some cases are more appropriately handled by such a society. The Ministry's assurance will not apply if the defence of the doctor is undertaken by the defence society, and will be subject to the Minister being informed at once of any threatened proceedings and having complete control over the conduct of the defence.

In England Now

A Running Commentary by Peripatetic Correspondents

MY daughter-in-law is expecting a baby, and I said wasn't she lucky to be having it in such a famous London hospital where she could be sure everything would be all right. My daughter-in-law said yes she supposed so, but doctors didn't know everything. In fact there were some things she wished they knew a little more about. She would tell me.

She goes every week to the hospital and a month ago the doctor said she would have the baby in a week. Then she went back in a week and another doctor said you can't possibly tell for certain and she might easily be another fortnight. So my daughter-in-law went home again.

The next time she went a third doctor said she ought not to be alone and was there anybody with her when her husband was away at work? My daughter-in-law said she would get her mother to stay with her in the day-time, though it was not very convenient.

The next week the mother of my daughter-in-law said she was not coming any more. She weighed fifteen stone and lived thirty miles away and in this heat she couldn't stand the tubes and the buses. And anyway my daughter-in-law had the telephone, hadn't she?

At the hospital a fourth doctor said they had better induce her and would she please come in tomorrow. My daughter-in-law went and they did all sorts of queer things to her, and while they were at it one of the other doctors popped his head round the door and said hullo, it's you is it, and he'd better take her over. So he took my daughter-in-law over and said nothing seemed to be happening so she could go home now.

There is a board up in the hospital saying if you notice anything unusual you should tell the doctor at once. My daughter-in-law said the baby made queer clicking noises inside her at night just as if it was pulling its fingers and making them crack. So she told the doctor and asked him what caused it, and the doctor said it was caused by the baby pulling its fingers and making them crack. My daughter-in-law did not think this was funny.

My daughter-in-law says doctors shouldn't argue over your tummy about whether the baby is lying right, because it rather frightens you if you are having a baby for the first time, doesn't it? And anyway she knows she is a left occipito-posterior because she read it on the folder before sister came and snatched it away and said goodness what would doctor say if he saw her. And that's another thing, my daughter-in-law said. If they don't want you to read your folder they shouldn't give it to you and then leave you lying on a couch for half an hour with nothing to do. Because what do they think a girl is going to do all that time.

My daughter-in-law said of course they knew all about having babies there, but she did think if these young doctors studied psychology a little as well so that they knew what their patients were thinking, it would be a good thing, if I saw what she meant.

I thought I did.

* * *

"I am not addressed as Fellow, my lord. I am a Master Executioner . . ."

You may remember these words as the end almost of the skilful cascade of falling anticlimaxes by which Shaw lets us down from the tension of the trial scene in *Saint Joan*. But I am more concerned with it as authority for the relative grading of the letters after our names. A Fellow, it appears, is less than a Master. Now a Master as everyone knows is something between a Bachelor and a Doctor, and a Member is less than a Fellow. Yet there are people, knowing one to be an M.D., who dare to suggest one would be better with an M.R.C.P. as well.

* * *

He was a shunter, in hospital for treatment of a peptic ulcer. The history-taking was thorough, and he was asked whether he had been subject to any stress at the time of onset of his symptoms. "Yes, there was something," he said, "I 'ad a bit of bad luck. Drove into the side of another train where the lines converged—pushed 'im clean off the road and telescoped three carriages. Week later, I went into the back of a train; saw the signal but didn't stop; why I don't know to this day. And five days after that, bless me if I didn't leave me train too near a crossing and the other bloke 'it me—my fault of course. Didn't do much damage that time, I didn't. Just smashed up the driving cabin. No, can't say I did get dyspepsia just then. Takes a lot to put me off me food. Besides, these things 'appen every day. How much was the damage? About £27,000 worth."

I thought of the sleepless nights caused by the £8 bill for beating out the door of my Morris Minor . . .

* * *

At some time in the 1860s the youngest daughter of a Truro physician contracted scarlet fever. She recovered, but one of her brothers died of the disease. After this experience she became a diffident and apprehensive child; and when she was dying, sixty years later, she said to her firstborn son, "You don't know what a comfort it is to think that I am never going to be shy again." Although a dutiful wife and a good mother, she had withheld from her family all outward appearance of affection.

When her son, at the age of nine, was sent to boarding-school, he was a sensitive and timid child eagerly seeking the love denied him by his mother; instead he encountered, nightly and for six terms, the remorseless cruelty of other boys. The life of imagination became his real existence, and he fed it daily with innumerable novels and romances. This day-dreaming disturbed his studies and prevented the acquisition of the common skills and the ordinary practicalities of modern life. Throughout his life his imagination continued to be preoccupied by terror and obsessed by cruelty. He described his undergraduate career at Cambridge as shabby and furtive with "no honour and much timidity." There, however, he first practised that extraordinary impetuosity in search of friendship which brought him some distress but greater happiness. "Er liebte jeden Hund, und wünschte von jedem Hund geliebt zu sein." All men were his fathers and brothers; but no woman was to be his lover, for maternal rejection destroys the sexual impulse.

He liked his food and when "out to tea, he would gleefully eat half-a-dozen macaroons like a guilty schoolboy"; and at forty-one, developing diabetes after the death of his mother, he was neglectful of diet and erratic with insulin. He was sympathetic, generous, industrious, intelligent, and eloquent. He was ambitious, acquisitive, vain, obtuse, and disposed to tantrums of great violence. He died, as my readers will have forecast, of coronary thrombosis. His name was Hugh Walpole, and I have just been reading his biography which Rupert Hart-Davis has written in friendship, wisdom, and restraint.

* * *

Doctors' children are commonly, if erroneously, supposed to be less healthy than the offspring of non-medical parents, and I sometimes think I detect among my friends a malicious pleasure in discovering that the children of an embryo psychiatrist are at any rate not better behaved or conspicuously better adjusted than their contemporaries. The other day, a neighbour of mine described to me the small schoolfellow of one of her own children as being the worst mannered and most horrible child she had ever met. "But" she added, "then I found out that the father is a psychiatrist, so of course the child is allowed to do exactly what it likes and has never been taught any manners."

Naturally I don't accept this as final, or even fair, but certainly the psychiatrists haven't yet given us all the answers. Meanwhile enlightenment sometimes comes from unexpected sources. Last week, over the dinner table, an unusually intelligent old lady of 80 quoted the wisdom of her father's coachman, who had helped to bring the whole family up. "Children" he said, "must be with other children. Only children can be sufficiently unkind to each other." I find this a consoling thought when our daughters beat each other up, steal each other's possessions, insult each other with the worst words at their command, and, in fact, give every evidence of having a psychiatrist for a father.

Letters to the Editor

THE SITUATION OF THE MENTAL HOSPITALS

SIR,—The scarcity of beds in mental hospitals is due to lack of nurses, but, as you remarked last week, "the remedy is not yet in sight" and "the problem of recruiting mental nurses needs special study." This study is bound to take time, and any decisions will take still longer to implement. During all this time the beds that are needed now will not be available.

There is, however, one way in which many more beds could be made available without recruiting a single extra nurse, and that is by discharging many of the harmless chronics who now make up a big proportion of the permanent residents in every mental hospital. If local authorities, together with the Ministry of Health, would organise "day hospitals" more or less on the pattern of the one in Blackfriars Road,[1] these chronics could be effectively supervised, occupied, and treated by day, and at night could be sent to their homes or to relatives or friends accepting responsibility for them. As an immediate temporary solution, this would enable acute cases to obtain the urgent treatment they need, thus perhaps preventing chronicity. In many cases the chronics and their relatives would welcome the release from hospital. Not only would this effect a general all-round economy, but also it could help to dispel the mental-hospital stigma, proving how many mental patients need not remain incarcerated for life.

Manchester. J. F. WILDE.

"A.P.F. EFFECT" AND ISONIAZID

SIR,—Dr. Mosonyi and his colleagues[2] say that streptomycin sometimes improves the health of children to an extent which is apparently unrelated to the type of disease for which it is given or to the eventual outcome. They do not enumerate these streptomycin-responsive diseases; but if they are the same as those I have listed as responsive to "mycin" or adrenocortical hormones[3] the statement will have my full support.

At hospital conferences, when I have presented patients with leukæmia, Hodgkin's lymphoma, disseminated lupus erythematosus, or rheumatoid arthritis, which has apparently been brought into the remissive phase by mycin administration, I have been assured that, if correct, my observations would mean that all these diseases are due to "infection" by "mycin-susceptible" viruses or bacteria. Even admitting that all the mycins —even streptomycin—are "broad spectrum" antibiotics, it is of course impossible to take this explanation seriously. In the United States a large proportion of our domestic poultry, swine, and fur-bearing animals have had their growth-rates increased by the addition of a mycin supplement, under the name of animal protein factor (A.P.F.), but one can hardly suppose that all this improvement is due to the cure of active infections from which they previously suffered.[4]

A closer though not complete approximation to the true rôle of what (in animal husbandry practice) has been termed the A.P.F.-mycin effect may have been given by Selye[5] in citing evidence that streptomycin,[6] penicillin (which is an A.P.F. in chickens), and terramycin[7] are non-specific "stressors" in his adaptation mechanism scheme. To make the adaptation theorem explain the facts fully, we need to redefine the term stressor.

Obviously the major rôle of an antibiotic is not that of a *non-specific* stressor, for then its administration would in itself constitute the stress, and all antibiotic administration—even to normal individuals—would elicit an adrenocorticomimetic response. We know, however, that in the perfectly intact (i.e., the non-stressed) individual mycin administration does not have much effect; nor does the administration of dehydroascorbic acid, a corticomimetic agent under certain circumstances,[8] have much effect in the "unsensitised" (i.e., non-stressed) animal, according to Dr. Kelemen and his co-workers who seem to have recognised the necessity of designating the subject's state in the interpretation of general adaptative responses.[9]

The failure of a patient with adaptative disease to react properly to his stress situation is remedied by ingestion of A.P.F. which seems to work by curtailing absorption of proteose from the lower bowel. There is now strong indirect evidence that certain types of hyperproteosæmias, derived intestinally or otherwise, may competitively block the unique polypeptide synthesis by which the anterior pituitary elaborates its corticotropin.[10] Any A.P.F., by substitution of a predominantly saccharolytic intestinal flora, may mitigate hyperproteosæmia from this source and thus permit an adrenocorticomimetic response in a stress situation.

The above explanation of the operation of mycin, or other A.P.F., in adaptative disease is now put forward for a very practical reason. It appears that isoniazid, the recently exploited "anti-tuberculosis" drug, is a potent A.P.F. in vivo. Though presumably devoid of any capacity to inhibit, in vitro, the development of clostridial or coli-aerogenes organisms, it nevertheless may promote implantation of a predominantly saccharolytic intestinal flora. Hence the same remissive tendencies previously produced by mycin ingestion in patients with lymphoma and collagen-vascular diseases are being duplicated by isoniazid administration. It is to be hoped that this last fact will not be seized upon to "prove" the universally tuberculous nature of adaptative disease. After all, the days are not long past when everything except childhood exanthems was explained away as a manifestation of tertiary syphilis.

Laurelton,
Long Island, N.Y. ROBERT D. BARNARD.

HALLUX VALGUS

SIR,—We are grateful to Mr. Turvey (Aug. 2) for his criticism of our radiographic method.[11] We are ourselves acutely conscious of its limitations, which have been dealt with more fully in papers referred to at the end of our text.

Two observations may go part of the way to meet his criticism:

1. There is no association between high longitudinal arch and increase of hallux valgus. In fact the opposite holds.
2. It is not, we think, possible to get any reliable information whatever about the size of the first intermetatarsal angle by any external measurement of any kind.

This leaves his objection that a high longitudinal arch is associated with an apparent diminution of intermetatarsal angle. In any future survey statistical analysis of this point by means of the partial-correlation coefficient might be advisable. We doubt whether, in fact, this factor will be of much significance, and would only add that, however much radiography may be a *pis aller*, it is at present the only available method of making any measurement at all.

PANCREATICOGASTROSTOMY

SIR,—In their paper (Aug. 9), Professor Ingebrigtsen and Professor Langfeldt say that they "resected the antrum of the stomach so that it contained no free acid postoperatively." They make the same point in their summary. Their use of the phrase "extensive resection" of the antrum in the second place suggests that the word does not refer to the pyloric antrum in Norwegian nomenclature as it would in British, but in any case it is difficult to see how any partial resection of the stomach, however extensive, could get rid of the gastric hydrochloric acid unless the vagi were resected at the same time.

London, W.1. HENEAGE OGILVIE.

MEPHENESIN IN INTRA-OCULAR OPERATIONS

SIR,—As is well known, in intra-ocular operations it is essential that the extra-ocular muscles should be relaxed, thus keeping the vitreous back and preventing the patient from "squeezing" the eye.

I have, in the past, hesitated to use curare for this purpose. Some two years ago, however, I started to use mephenesin ('Myanesin Elixir'), which I have found produces relaxation with no danger to the patient. I have used this preparation in 26 cataract operations, 22 glaucoma operations, about 70 iridectomy operations, and 4 cases of nystagmus.

One tablespoonful of the preparation was administered two hours before the operation, followed by a further tablespoonful one and a half hours later. This dosage was used whether or not tension was present. Half an hour after the second dose, the eye muscles became relaxed and the patients experienced a slight "numb sensation" throughout the body. During operation the vitreous remained in place and did not present forward, and the operation could proceed with ease and safety. In the cases of nystagmus, mephenesin either stopped oscillations or minimised them in 2 children, lessened them in a girl of 15, and appeared to abolish them (after repeated administration) in a man of 45.

I should be interested to know whether anyone else has tried mephenesin in these conditions.

Coptic Hospital,
Cairo, Egypt. ABDEL MESSIH GIRGIS.

THE PROSPECT OF GENERAL PRACTICE

SIR,—Your anonymous and egotistic correspondent (Aug. 16) has decided that his "intellectual thirst" cannot be satisfied in general practice as it is, and goes on to give about the most distorted account of a G.P.'s life and work I have ever read. To answer his 4 points in order:

1. After enlarging on his skill and intellect, he states: "I shall be too busy to examine or follow any case adequately." I would say that any G.P. who fails to examine or follow any case adequately will very soon be in trouble. If we organise our work properly by making special appointments, &c., we can always ensure that a patient requiring a detailed examination is given it at leisure. Now that X-ray and laboratory facilities are generally available we can fully investigate the majority of our cases without troubling the consultant.

2. If this is his idea of a G.P.'s family life even before "Danckwerts," then I am truly sorry for him. Has he never heard of arrangements with his colleagues?—but, of course, he does not trust them (see point 4). Has he never heard of a rota for night work, group practice, or partnership?

3. "Whatever insult, stupidity, thoughtlessness, or unnecessary demands he [the State patient] may submit me to, I must smile and comply." Does he really think G.P.s are as spineless as this? Anyone with this outlook would soon collect a practice of malingerers and be treated by his patients and colleagues with the contempt he deserved. Every practice must have some discipline, and the patients respect their doctor for applying it.

4. "...if an influential competitor gets a seat on the Regional Board not only are my hopes of advancement killed, but my very livelihood endangered." This is an amazing statement, and I confess I cannot conceive how a G.P. could possibly be affected in any way by a "competitor" being appointed to a regional board. Sir, may I ask your anonymous correspondent to give chapter and verse for his statement and explain what he means? For his information a G.P.'s authority in the N.H.S. is the executive council, and we are only too grateful for the work and time spent on this council by those of our colleagues who are appointed to it. If this statement is indicative of your anonymous correspondent's ideas of how G.P.s treat each other, then it is no wonder that he has not considered working an off-duty or holiday rota with his neighbours.

With his suggestion that there should be more research in general practice I have no quarrel, but I strongly object to his picture of general practice, and his condescending attitude as exemplified by his suggestion that a G.P. would be ridiculous in a professorial chair. I can think of many G.P.s who would bring dignity, knowledge, common sense, and much-needed liaison as professors in our universities.

Research in general practice will, in my opinion, best be stimulated by increasing liaison between hospital and G.P.s, and by making G.P. beds available in hospitals. It will not be helped by articles such as your anonymous correspondent's, which can only have the effect of discouraging this desirable and necessary liaison.

Wingerworth, near Chesterfield. J. F. HANRATTY.

PRESERVATION OF ARTERIAL GRAFTS BY FREEZING

SIR,—The article by Professor Hufnagel and myself[1] included a reference to the work of Smith and Parkes[2] at Mill Hill on recovery of frozen stored ovarian tissue and red blood-cells. Our comment that "survival is quite unpredictable, even with constant technique," though it certainly applied to previous methods of frozen storage, does less than justice to the work of the Mill Hill group.

A recent visit to that centre confirmed that the glycerol-saline technique provides consistently viable tissues after storage. Ovary, sperm, and testis, and some endocrine tissues seem to be perfectly preserved. It is to be hoped that this method may soon be applied to problems of stored functioning transplants in man; such tissue preparations are now being banked along with the arterial grafts in this department.

Surgical Unit,
St. Mary's Hospital, London, W.2. H. H. G. EASTCOTT.

FLYING AND LIFE ASSURANCE

SIR,—A peripatetic correspondent writes in your issue of July 26:

> "I wonder how many of my peripatetic colleagues . . . realise that if they fly more than 15,000 miles in the course of one year they are automatically depriving their dependants of all benefits under their F.S.S.U. scheme should they be involved in a fatal accident? Apparently all the leading life-assurance societies have a clause in their policies which imposes this limit on flying unless an extra premium is paid."

This conveys an entirely wrong impression, since British life offices issue, whenever possible, policies unrestricted as regards airline travel. So far as I am aware, no life-assurance policy issued in this country, whether under the F.S.S.U. scheme or otherwise, would contain any clause by which cover would cease after the policy-holder had flown in one year 15,000 miles, or indeed any other distance.

The future flying prospects of a proposer for life assurance are elicited at the time of his proposal. In the great majority of cases the expected yearly amount of passenger flying is less than 15,000 miles, and the issue

---

1. Hufnagel, C., Eastcott, H. H. G. *Lancet*, 1952, i, 531.
2. Smith, A. U. *Ibid*, 1950, ii, 910. Smith, A. U., Parkes, A. S. Ibid, 1951, ii, 570.

in such cases of policies unrestricted in respect of airline travel is normally automatic. If the expected amount of passenger flying exceeds 15,000 miles per annum, the usual course is for a quite small additional premium to be paid in order that a policy without restriction on airline travel can be issued.

Under an unrestricted policy a life office would expect to meet in full any claim arising out of airline passenger flying, no matter how much such flying the policyholder had done, provided of course the office was satisfied that his answers at the time of his proposal were given in good faith.

J. H. KITTON.

OXYGEN TENTS

SIR,—May I be allowed to correct several misleading impressions given to users of oxygen tents by your special article, Ingenuity in Whitechapel (Aug. 2, p. 237).

While such costly tents as those referred to (£180–237) may be available for sale, the majority of hospitals and institutions have long known that a range of the most modern completely equipped oxygen tents can be bought at a fraction of such prices through my own organisation. Oxygenaire Ltd.—probably the largest manufacturers of oxygen tents in the British Empire—i.e., from £30 to £135 according to size. As with most other manufactured goods, cheaper qualities of oxygen tents might possibly be introduced at lower cost, but not if all the modern refinements of construction and performance—now almost universally demanded—are to be included.

From our twenty years' specialisation in the manufacture and supply of oxygen tents, it is not our experience that hospitals in this country find the hire of tents as expensive as your article implies, when all the factors behind a day-and-night rental service are taken into account. Our own service, for instance, includes the immediate delivery of a tent to any part of the country with qualified operators; free instruction and demonstration in the ward; free inspection and maintenance of equipment; the free provision of medical films and filmstrip lectures for training purposes; the benefits of continuous research and the development of improved methods and apparatus; and frequent non-profit-making coöperation in experimental work in hospitals.

I am somewhat dismayed that the results obtained with the tents described in the article should be regarded as "almost identical with those from a standard oxygen tent," since they fall very far short of the results to be obtained with tents of our manufacture—and which are indeed expected of our tents by the majority of hospitals.

If authorities using our tents would avail themselves of the free inspection and maintenance service we provide with our equipment, they would readily appreciate the higher efficiency that can be attained when a tent is overhauled and restored to our own critical standards of operation.

8, Duke Street, London, W.1.

G. W. HIGGS
Managing Director
Oxygenaire (London) Ltd.

***We have shown Mr. Higgs's letter to the surgeon at the London Hospital who was responsible for the tests made on the oxygen tents. An extract from his reply is given below.—ED. L.

"The dismay expressed by Mr. Higgs is surprising, since the results we obtained correspond completely with the aims expressed in the useful little booklet 'Oxygen Therapy,' published by Oxygenaire Ltd. It must be explained that we did not set out to obtain maximum oxygen concentration levels, and have not subjected our tent to such purely theoretical trials, as we see no practical advantage in so doing. We took one of our tents and an Oxygenaire tent, and ran a series of identical tests on both, supplying the oxygen at the rate recommended by Oxygenaire Ltd. The detailed figures were:

Tent	*Oxygen concentration after*		
	20 min.	*60 min.*	*120 min.*
L.H.	39·9%	48%	48·1%
Oxygenaire ..	40·2%	47·6%	48·1%
	Carbon dioxide concentration (max.)		
L.H.		1·7%	
Oxygenaire ..		1·72%	

Temperature and humidity tests both showed a steady line with each tent. As we did not perform the tests simultaneously, but first tested our own and then the standard pattern, the figures do not correspond, but in neither case did the temperature or humidity rise significantly.

We did these tests purely to satisfy ourselves that our tent was as efficient *in our hands* as the standard model, as sold; and for no other reason. Better figures are no doubt obtainable with both models. We were only concerned to be sure that the results were good enough for use on patients requiring oxygen therapy, when the tent was erected and run by our normal nursing staff, with due regard to economy in oxygen. We satisfied ourselves on these grounds; and only after a year of hard, steady use did we feel that other hospitals might care to benefit by our experience."

PLEA FOR PSYCHOTHERAPY

SIR,—May I take up one or two points in Dr. Mullner's letter of Aug. 16?

I had no intention either of decrying the value of modern physical treatment in psychiatric cases, or of denying the need for research to give greater knowledge and certainty. I maintain merely that, in our enthusiasm for the physical approach, we should not forget that psychotherapeutic methods have their proved value and are, to say the least, no more empirical than many physical methods. I hold no brief for psycho-analysis on Freudian lines, but on the contrary, believe in the utmost flexibility of technique. Until we know more, we are not justified in withholding any form of treatment which promises benefit, even though we cannot argue its value as scientifically as we should like.

I would query the implication by Dr. Mullner that confession is equivalent to Freudian psycho-analysis (the word psycho-analysis of course denotes the Freudian procedure). Surely the first deals with the conscious, and the second with the unconscious, content of the psyche.

London, W.1.

MARION GREAVES.

FEEDING DISORDERS IN INFANTS

SIR,—While I feel sure that Miss Morrison and I would find some points we could agree upon in the care and treatment of infants suffering from feeding disorders, yet when we come to the interpretation of these disorders it is obvious that we think quite differently.

Most of Miss Morrison's letter (Aug. 9) is little more than a direct negative to the points I tried to make in the article of July 19. Briefly, the points Miss Morrison endeavours to establish are that the feeding disorders are mainly due to a wrongly balanced mixture, that each infant requires a varying type of modification of the food to meet its own special needs, and that overfeeding is something that has to be carefully avoided. On the other hand, I put forward a plea for more generous feeding with food of good concentration, and I tried to make out a strong case for the belief that most feeding disorders were due to wrong feeding technique and to under-feeding. In this I find myself strongly supported by Dr. Wood in his letter last week; and I should like —very belatedly—to take this opportunity of saying how much I agree with his article,[1] which dealt in a practical way with some of the causes of vomiting in infancy.

Leeds.

C. W. VINING.

Obituary

ALFRED SCHWEITZER

M.D. Cologne, Ph.D., D.Sc. Lond.

Dr. Alfred Schweitzer, reader in experimental physiology at University College, London, was killed in a mountain accident in the Dauphiné on Aug. 9. He was 43 years of age.

Schweitzer was educated in Germany and took his M.D. at Cologne in 1932. In 1934 he worked under Koch in the Kerckhoff Institute at Nauheim where he acquired an interest in the physiology of the carotid sinus. At this time he also wrote his book, *Die Irradiation Autonomer Reflexe*, which was published in 1937.

He came to England in 1935 and immediately settled down to a most fruitful research partnership with Prof. Samson Wright at the Middlesex Hospital Medical School. Their studies on the actions of acetylcholine and anticholinesterases on the reflex activity of the spinal cord marked the first experimental attack on the problem of chemical transmission within the central nervous system. These investigations continued up to the war when Schweitzer turned his attention to more immediately pressing problems and worked with Prof. G. A. H. Buttle and Prof. Alan Kekwick on the value of plasma and serum in the treatment of experimental hæmorrhage.

In 1940 he went to the department of physiology in Leeds, where he remained as lecturer until 1947. He there worked with Prof. Albert Hemingway on the isolated kidney and they studied the cardiac output in exercise. During the latter part of his sojourn in Leeds he worked with Dr. Eric Neil on many aspects of the physiology of the sino-aortic nerves. Schweitzer continued and expanded these studies when he was appointed as reader in experimental physiology under Sir Charles Lovatt Evans at University College. In conjunction with Dr. Michael de Burgh Daly he had recently demonstrated reflex effects from the carotid sinus and carotid body on bronchomotor tone, and his development of a technique for measuring blood-flow through the minute carotid body was a technical *tour de force*. Schweitzer and Neil were writing a book on the baroreceptor and chemoreceptor activities of the sino-aortic nerves.

Besides his versatile research activities Schweitzer was a wonderful teacher whose enthusiasm and powers of expression were reinforced by a real anxiety to make his point clear to everyone, so that no trouble was too great to achieve this purpose.

From the day of his arrival in this country he wanted to attune himself to the British way of life. It seemed perfectly natural for him to accept our ideals and aspirations, and he was never in any sense of the word a foreigner.

Schweitzer loved people and was the most delightful companion imaginable. He wanted everyone to be his friend, and it was not his fault if they were not. His kindness and generosity were proverbial, and if he did occasionally become indignant about something it was always on behalf of someone else. It is indeed most tragic for his wife and family and for his innumerable friends that a man of such inspiring character should be lost to us at the very height of his powers.

He was gifted in many ways. He was a first-rate violinist and had a profound knowledge and understanding of music, which was one of his great passions in life. He was a most experienced and able mountaineer, and in recent times he went annually to tackle the formidable peaks of the Dauphiné. These arduous holidays meant much to him, and they seemed to give him inspiration for the rest of the year. It is fitting that he should be buried in a village among the mountains which he loved. C. A. K.

LIONEL NATHAN GRUNBAUM

M.A., M.B. Camb., M.R.C.P.

Dr. L. N. Grunbaum, an assistant chest physician at Edmonton, died on Aug. 2, after an attack of poliomyelitis.

He studied medicine at the University of Cambridge and at St. Bartholomew's Hospital. After qualifying in 1939 he spent a year doing house-jobs in the Barts sector before he turned to pathology at the Radcliffe Infirmary, Oxford. While there he produced one of the first of a series of Christmas pantomimes of great merit performed during the war by the Oxford clinical students. From 1942 to 1946 he served in the R.A.M.C. with the rank of major as a specialist in pathology, but after the war he felt the need for the direct personal contacts between patient and doctor which clinical medicine affords. He took his M.R.C.P. in 1949 and he chose chest medicine as his specialty. Later he held registrarships at the Westminster Hospital and at Fulham chest clinic. He was working as a chest physician at Edmonton and was preparing a thesis on Mantoux conversion of tuberculous contacts at the time of his death.

C. M. F. writes: "Lionel Grunbaum brought to medicine an understanding of many things. Profoundly musical, he was an accomplished pianist. A most shrewd judge of character, he showed a humorous tolerance of human foibles. It was his great interest in people that led him to forsake the humanities, in which he had taken his degree at Cambridge, and start upon his medical course at Barts later than his contemporaries; and his deep concern for the material well-being of those less privileged than himself led him to argue and work for Socialism. His fellow-students at Barts will recall many loud-voiced arguments on politics with him, which often verged on the acrimonious until his sense of humour came to the rescue, and agreement, or agreement to differ, was reached with an increase of understanding on both sides. He will be remembered by many friends among his colleagues, his patients, and in many other walks of life, orthodox and bizarre. We shall miss his shrewdness, his sympathy, and his loyal friendship; but the liveliness of his memory will go with us, and he will not have lived and worked, played and talked, in vain."

MR. H. E. MOORE

H. O.-C. writes: "One of H. E. Moore's outstanding traits was his modesty. No doubt this is the reason why his remarkable contribution in the field of rehabilitation received such mediocre recognition in his lifetime. The value of curative workshops in military orthopædic centres had been well recognised by Sir Robert Jones in the first World War, and after the war quickly forgotten by most surgeons. Moore was the real pioneer of the rehabilitation of injured workmen in this country. He, almost alone, appreciated that a half-hour spent receiving passive treatment three times a week in the massage department of a hospital was neither the best way to mobilise joints and restore muscle-power, nor the way to instil into patients the confidence without which they could not recover. Indeed apathy and despair were often induced—and still are—by passive methods of treatment. It has taken nearly thirty years, the investigations of many committees, and another world war to impress this obvious lesson on our profession and its auxiliaries.

"Moore was appalled by the conditions of railway workers coming to his hospital at Crewe; after long periods of 'treatment' elsewhere most of them were dispirited and seemingly incapable of improvement. In the early days of his work at this hospital, of 165 patients of this type 115 were returned to their former employment after an average period of seventeen days' rehabilitation. In those days this was a startling achievement accomplished entirely by active exercises with simple gymnastic apparatus, and above all by Moore's dynamic driving force which inspired confidence where hope of recovery had long been lost. This same technique and the instigation of this same spirit—the will to recover—he brought to the rehabilitation centres of the Royal Air Force during the second World War. Before then it had been confidently predicted that all injured air-crew personnel would be useless for further military duties, so seriously complicated and multiple were their injuries. True enough their injuries were complicated and multiple, but 77% of injured airmen were returned to full duty. It is therefore hardly surprising that the Royal Air Force has with great benefit continued its rehabilitation centres to this day embodying everything taught by Moore. Throughout Britain and the British Commonwealth there are old R.A.F. pupils of his, all too few, carrying on his principles and emulating his practice.

It is sad, however, to see how slow the development rehabilitation facilities has been in civilian practice. a letter written a few weeks before he died Moore plored this tardiness 'as a brake on the economic overy of the country by an unnecessary wastage of n-power, and a diminution of the span of human ppiness and the enjoyment of living'; and he exhorted to spare no effort to advance the importance of a re comprehensive remedial service for the injured.

"Moore was an inspiring companion and a most lightful and coöperative colleague. His life work, rformed so efficiently and effectively, is a lasting bute to his philosophy as a staunch believer in the wer of mind over matter. We often deplore the opagandist in medicine, but it is a thousand pities at Moore's modesty prevented him from being a more tspoken evangelist of what he knew so well to be ue—that men and women could be restored to working pacity by simple, practical, but essentially personal ethods, methods which he lived to see abundantly oven in the hard schools of industry and war."

Public Health

Poliomyelitis

POLIOMYELITIS notifications (uncorrected) in the week ded Aug. 9 (the 32nd week of the year) were (previous eek in parentheses): paralytic, 167 (139); non-aralytic, 83 (91): total, 250 (230).

The following table compares this year (up to and cluding the 32nd week) with the preceding five years.

Year	*Total cases up to and including 32nd week*	*Cases in 32nd week*
1947	2252	624
1948	912	39
1949	1457	254
1950	2986	393
1951	1511	112
1952	1910	250

Slaughter of Horses

The Public Health (Meat) (Amendment) Regulations, 952, which come into force on Aug. 31, give effect to n announcement by the Minister of Food that horse laughterers would be required to notify authorities of heir intention to slaughter.

The purpose of the amending regulations is to put the laughter of horses, asses, and mules for sale for human onsumption on a similar basis to that of cattle, sheep, oats, and pigs. The chief requirement is that anyone ntending to slaughter horses, asses, or mules must give t least three hours' notice to the local authority. Where, owever, slaughter takes place at a particular place at xed times, no individual notices are required; and where immediate slaughter becomes necessary because of ccidental injury, illness, or exposure to infection, notice must be given as soon as possible before or after slaughter.

Responsibility for enforcing the Public Health (Meat) Regulations remains with the local authorities. The present amendments will help local authorities in their task of arranging for the inspection of horse-meat intended for sale for human consumption. Local authorities will also be placed in a better position to execute and enforce the provisions of the Slaughter of Animals Acts, which are designed to ensure that animals are slaughtered in a humane manner.

Revised Regulations for Sea and Air Travel

The Minister of Health has made certain changes in the regulations governing travel by sea and air.[1] The revision became necessary when the Fourth World Health Assembly adopted the International Sanitary Regulations,[2] which will replace the present International Sanitary Conventions on Oct. 1 next. Though the British regulations have not been under general review since 1933, no substantial alterations affecting the traveller have been made. The personal declaration of origin and health, at present required from all persons arriving by air, is to be abolished. The revised regulations will also come into force on Oct. 1.

Notes and News

DISTRIBUTION OF DANCKWERTS AWARD

THE additional remuneration for general practitioners for the period ended March 31, 1949, and for each of the years ended March 31, 1950, March 31, 1951, and March 31, 1952, and the provisional addition for the quarter ended June 30, 1952, is to be divided among executive councils in proportion to the amounts already allocated to them from the practitioners' fund for each of those periods—including the allocation for temporary residents. The distribution of each council's share of the additional remuneration among the doctors who were included on its medical list at any time between July 5, 1948, and June 30, 1952, will similarly be made in proportion to the amounts allocated to the doctors out of the council's practitioners' fund—i.e., excluding mileage payments. The amount due to each doctor for each period can conveniently be represented as a percentage of the amount already allocated to him. Further particulars of the procedure to be followed will be found in E.C.L. 65/52.

DOMESTIC SUPERVISION

THE hospital service probably employs more domestic workers than any other organisation in the country. As domestic labour today costs a good deal—though probably not more than it should—"wages" are a heavy item in the National Health Service budget. The Ministry of Health is rightly anxious that those who earn these wages should be efficiently and economically organised. In a memorandum on hospital domestic management (R.H.B.[52]91) the Ministry affirms that any hospital with a domestic staff of over 75 would probably save money by employing a domestic superintendent who would give all her time and attention to organising this large and important part of the hospital service.

Outlining the duties of a domestic superintendent, the Ministry suggests that she should be directly responsible to the matron, but should keep in close touch with the heads of all departments. Besides organising the work of the domestic staff she would be responsible for their engagement, training, and welfare. Supervision of the work and allocation of duties within the wards and departments would probably continue to be undertaken by the sisters and officers in charge. The Ministry do not however propose any hard and fast range of duties for the post. In a smaller hospital, for instance, the duties might well be combined with catering, and an appointment of housekeeper-caterer made. On the other hand in a large hospital the domestic superintendent might well require an assistant.

People with suitable qualifications for these jobs, the Ministry admits, are scarce and anyone with experience of large-scale domestic management should be considered; but ideally a domestic superintendent should have completed a two-year course in institutional management, should hold a degree or a recognised certificate or diploma in household and social science, and should have had one or two years' practical experience.

University of Cambridge

On Aug. 2 the following degrees were conferred:

M.D.—G. S. Crockett, M. A. Floyer, E. L. McDonald, K. N. V. Palmer, * J. S. Pegum, D. R. Smith.

M.B., B.Chir.—* D. M. E. Allan, J. D. C. Anderson, N. W. Ashworth, * P. A. J. Ball, Robert Baxter, A. W. Beard, Kathleen M. Bennison, M. H. H. Bishop, C. J. Booth, * M. J. Boyle, June E. Brett, * H. G. Britton, B. W. Broadhurst, David Bryant, * G. M. B. Bulman, T. F. Bushby, A. R. Butterfield, * G. R. C. Campion, * S. McC. Cannicott, * Harold Caplan, * J. B. Chapman, * Betty Chester, * W. J. Colbeck, * R. R. A. Coles, * C. E. T. Cones, A. S. Cooper, Betty R. Corbin, * P. F. A. Crawshaw, * R. G. Daniels, * J. G. Davies, * J. I. W. Davies, * R. J. L. Davis, * R. H. Davison, * P. J. Dawson, E. M. Douglas, * I. C. Dow, * Michael Dulake, * A. V. Dunlop, * Warren Eade, J. H. Edwards, * J. R. Edwards, * J. N. T. Evans, R. T. D. FitzGerald, * J. R. Flury, * H. W. S. Francis, * O. H. French, * Nathan Gee, I. M. Glynn, * Rainer Goldsmith, Peter Griffiths, Eric Hainsworth, Thomas Hall, * Douglas Harrett, * Rex Harrison, * D. S. Harry, * E. P. Hilary-Jones, * A. L. Hilton, * John Innes, * D. S. Jeffery, * J. M. A. Jepps, * J. H. Jones, * D. H. Kay, * E. I. Kohorn, J. S. Lewis, * James Liddell, * J. S. H. Lodge, * A. B. Lowther, * P. J. Lyne, * J. M. S. McCoy, * J. A. McHardy, * P. J. McQuade, * Roger Mangnall, * R. J. Mather, * M. K. Mead, * G. C. Metcalfe, * J. F. Newcombe, * R. C. Norton, J. O. Ojukwu, W. N. B. Parker, J. E. Phillips, * Cyril Rashbass, * T. W. Rayner, P. S. Reay-Young, J. M. Rigg, J. H. Robson, R. W. Ross Russell, Vishnu Sarma, * J. H. Sewart, * C. A. Sharples, G. M. Shaw, Hilary J. Shimmin, * M. P. Siddons, J. M. Simister, * F. V. Simpson, G. W. Smallcombe, * R. L. Smith, R. J. Spray, * R. M. Standish-White, C. M. Stafford, * J. W. M. Stone, * J. H. Swallow, D. G. Thomas, * M. L. Thomas, D. H. Trapnell, * B. G. S. F. Vergano, G. I. Verney, D. G. D. Vint,

Renal Association

At a meeting of this society to be held at 4.30 P.M. on Friday, Sept. 19, at the Ciba Foundation, 41, Portland Place, London, W.1, Prof. J. G. G. Borst (Amsterdam) will speak on *Electrolyte and Water Balance with Relation to the Kidney.* Invitations may be had from Mr. John Sophian, 66, Harley Street, W.1.

Ability of the Disabled to Work

This topic has been chosen as the theme of the residential course which the British Council for Rehabilitation is to hold, with the University of Bristol, at Manor Hall, Lower Clifton Hill, Bristol, 8, from Sept. 9 to 11. Further particulars may be had from the secretary of the council, Tavistock House (South), Tavistock Square, London, W.C.1.

Central Midwives Board for Scotland

The board is to be reconstituted on March 1, 1953, in accordance with the recommendations in the report of the Midwives Working Party in 1949. The new board, like the old, will consist of 16 members, but 7 instead of 4 will be practising midwives. The Secretary of State for Scotland will appoint 3, and midwives practising in Scotland will elect the remaining 4. This will be the first time that midwives have elected members to their governing body. The other 9 members will be representative of medical bodies, local authorities, the universities, and the hospital services.

Singapore Pædiatric Society

This society has been formed to advance the knowledge and practice of pædiatrics and to promote child health in Malaya. It is open to all doctors registered in the Colony of Singapore or in the Federation of Malaya. The following office-bearers have been elected: president, Dr. G. Haridas; vice-president, Prof. E. S. Monterio; hon. treasurer, Dr. William Heng; hon. secretary, Dr. G. Keys Smith (St. Andrew's Mission Hospital for Children, Singapore); members of the executive committee, Prof. J. A. P. Cameron; Dr. Tan Jiak Hoon, Dr. W. B. Young, and Dr. Wong Kin-Yip.

Ministry of Health Circulars

Consultant in Administrative Charge (R.H.B.[52]93).—Where there is more than one consultant on the staff of a special hospital department the Ministry considers it advisable that one should be given administrative responsibility for the organisation of the auxiliary professional and technical staff and for the care and custody of apparatus and equipment. The appointment would not confer any authority over the clinical freedom of other consultants, nor carry any additional remuneration.

"Private" Work in Hospital Pathological Laboratories (R.H.B.[52]92).—This memorandum sets out the types of work which come under this designation.

W.H.O. Regional Committee for Africa

The first meeting of this committee to be held in Africa opened on July 31 in Monrovia, Liberia, under the chairmanship of Prof. Francisco Cambournac, of the Institute of Tropical Medicine, Lisbon. Presenting his report to the delegates of eight member States, Dr. François Daubenton, director of the regional office, said that it was hoped to move the regional administration from Geneva to Brazzaville in September. He added: "This is not a land in which to introduce preconceived ideas. Here the people have developed along their own lines and will further develop, perhaps for historical reasons, in another direction from the rest of the world—and they have the right to do so. The international specialist agencies must give them all the facilities possible and applicable, but the people of this sympathetic, vast country have the right to develop their own philosophy. Only in this way will they be happy. Physical well-being may, perhaps, be prescribed or even introduced, but mental and social well-being can only be achieved with the understanding and coöperation of the people themselves, not by imposing foreign ideas. To assist in the attainment of the well-being of Africans remains the aim and duty of the W.H.O. Regional Office for Africa."

At the close of the meeting Professor Cambournac was appointed regional director in succession to Dr. Daubenton who will reach retiring age next year. Professor Cambournac will take up his appointment in January, 1954.

State University of Iowa

Dr. R. S. Duff has been appointed research assistant professor of internal medicine in the university college of medicine and university hospital, Iowa City, U.S.A.

Dr. Duff graduated M.B. with commendation in the University of Glasgow in 1943. He was elected F.R.F.P.S. in 1947 and he took the M.R.C.P. the following year. He has held a research fellowship in applied physiology at St. Thomas's Hospital, London.

University of Otago

Mr. M. F. A. Woodruff, assistant surgeon to Aberdeen Royal Infirmary and the Royal Aberdeen Hospital for Sick Children, and senior lecturer in surgery in the University of Aberdeen, has been appointed to the chair of surgery in succession to Prof. F. Gordon Bell, who is retiring at the end of this year.

Mr. Woodruff, who is 41, studied at the University of Melbourne, where his father held the chair of bacteriology. He graduated first in electrical engineering and then in medicine in 1937. After appointments at the Royal Melbourne Hospital, Queen's College, and the university, he graduated M.D. in 1940 and M.S. in 1941. With the rank of captain in the A.R.A.M.C. he served in Malaya and he was taken prisoner in 1942. During his imprisonment he studied deficiency diseases and his investigations have recently been published as a Medical Research Council report. In 1946 he joined the surgical professorial unit in Sheffield, and with a World Health Organisation travelling fellowship he later visited the U.S.A. and Canada. In 1948 he took up his present appointments in Aberdeen. He is also an associate examiner in surgery to the University of London, and in 1951 he gave a Hunterian lecture to the Royal College of Surgeons of England.

CORRIGENDUM: *Pancreaticogastrostomy.*—In the article by Prof. R. Ingebrigtsen and Prof. E. Langfeldt (Aug. 9, p. 270) the last two sentences in section (1) under the heading "Methods" should read: "Trypsin gives no turbidity with either of the two solutions. Erepsin gives turbidity with serum-protein, but none with peptone."

On Aug. 18 the staff of Broadmoor Institution presented a silver statuette to Dr. J. S. Hopwood, the retiring superintendent.

Appointments

FARQUHAR, J. V. L., M.R.C.S., D.P.H.: asst. senior M.O., Liverpool Regional Hospital Board's headquarters staff.

HOUSTON, J. C., M.D. Lond., M.R.C.P.: honorary asst. physician, Hospital of St. John and St. Elizabeth, London.

HUDSON, J. R., M.B. Lond., F.R.C.S., D.O.M.S.: honorary ophthalmic surgeon, Hospital of St. John and St. Elizabeth, London.

MCARTHUR, J. B. H., M.B. Lond., M.R.C.P.: consultant physician, St. Helens area, Liverpool [illegible] Hospital Board.

O'GRADY, T. P., M.B. N.U.I., D.P. [illegible] lth division no. 13 (Heywood), Lancash[illegible]

STRANG, C., M.D. Durh., M.R. [illegible] physician, Newcastle upon Tyne and [illegible] oups.

WILSON, R. N., M.B. Durh., D. [illegible] nworks Co. Ltd., near Nottingham.

Sheffield Regional Hospital Board:

BARCLAY, R. C., M.A. Camb., F.R.C.S.: consultant thoracic surgeon, Nottingham City Hospital and associated sanatoria.

FRASER, W. D., M.B. Glasg., F.F.R.: senior radiotherapist, the Hogarth radiotherapeutic centre, Nottingham General Hospital.

WALLS, H. E. C., M.B. N.U.I., D.M.R.T.: senior asst. radiotherapist, radiotherapy centre, Leicester Royal Infirmary.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

CAMPBELL.—On Aug. 8, at the Norfolk and Norwich Hospital, Norwich, to Elizabeth (née Morris), wife of Dr. J. A. Campbell—a daughter.

GRIFFITHS.—On July 23, to Vivienne, wife of Dr. F. E. D. Griffiths, of Kenilworth—a son.

LONGMORE.—On Aug. 17, at Shrewsbury, to Virginia (née Centlivres), wife of Dr. John B. Longmore—a daughter.

MARRIAGES

PEARCE—WOOD.—On July 26, at Oxford, John Kingsley Pearce, B.M., to Gwendolen Wood.

DEATHS

BROOKS.—On Aug. 15, at the Royal Sussex County Hospital, Gertrude Brooks, M.B. Lond., of Paygate, Woodmancote, near Henfield, aged 77.

HORTON.—On Aug. 13, at South Elmsall, Horatio Nelson Horton, M.D. Lond.

MARSH.—On Aug. 9, at Saltash, Cornwall, Ernest Louis Marsh, M.B. Glasg., of Shanghai.

WALKER.—On July 1, Herbert Walker, O.B.E., M.C., M.R.C.S., lieut.-colonel, R.A.M.C. retd.

THE DANGERS OF CHRONIC INACTIVITY IN THE AGED *

MARGARET HILL

BETWEEN 1871 and 1950 the number of old men and women has increased from $1^{1}/_{4}$ million to $5^{1}/_{2}$ million. It is estimated that in another 20 years there will be nearly 10 million people of pensionable age. Although in 1931 there were about four times as many young women as old, there are now only a little over twice as many. The burden on the social services and on the wage-earners will then be proportionately even heavier than it is now.

It is easy to think of old people as infirm old people, as these are so much more in evidence than the rest. Actually the number in hospitals and institutions is only between 3% and 5% of the total number of the old, although many others are desperately in need of care of some sort though not necessarily in institutions. There is a great deal of untreated disease in old people, and it must always be remembered that the process of growing old, apart from disease, produces biological changes, none of which are to the good. The problem which must be faced, unless an intolerable burden is to be borne by the younger members of the community, is how to prevent unnecessary illness in the middle-aged and elderly.

IMPORTANCE OF EARLY TREATMENT

Modern medicine is lengthening life in all countries, yet the best methods of dealing with chronic ill health in the old have not received sufficient attention. Much could be done at earlier stages and this is the all-important matter at the present time. The first preventive is to provide suitable living conditions so that old people may live independently and manage their own affairs for a longer period. From the point of view of activity which is essential to well-being there is nothing to excel the work involved in doing their own household chores, and the necessity for getting out regularly in all weathers to do their shopping. No contrived activities are so valuable or so health-giving as the necessary acts involved in living alone and independently. The emphasis must be on keeping the middle-aged young as it is difficult to rejuvenate the old; but even for these latter fresh air and exercise, no lying in bed unless absolutely necessary, good food, the absence of apprehension for the future, and the companionship of others of their own generation can do much to alleviate their disabilities.

I have had considerable opportunity of observing all this from a housing trust which has now been in existence for over twenty years. During this period some 320 people, most of them old, have been accommodated, and of the 48 who have died only 2 did so in hospital. All the rest stayed in their homes to the end. They were provided with visiting nurses and home helps where necessary. How much more economical for the community, and how much happier for the old people, if simple comfort and security of tenure in suitable surroundings enables them to live at home until the end.

HOUSING FOR THE OLD

While the more vigorous old undoubtedly like a little extra space and the privacy of a small flat, a single room with every convenience is better later on. I regret that in planning for the future, authorities and organisations are still preparing to provide perfection for the few and nothing for the rest. They could comparatively easily provide single rooms, with common bathroom and water closet for tenants on the same floor, either by building or by the conversion of larger dwelling houses, for a fraction of the cost of erecting blocks of self-contained flats. It is not even certain that the perfect flat is always appreciated or preferred. As a general rule it is far better for people of not more than two generations to live together, and undoubtedly it is happier for the older folk to live independently, and so remain active in the course of looking after themselves, rather than to try to adapt their lives to those of younger people or to become entirely dependent upon them for their care. Although there are happy family groups, especially in the country, on the whole old people prefer their own little home wherever possible. When the security of their own home is absent it may make them unwilling to go to hospital for essential treatment, fearing that they may lose both home and independence while away. Fear that old people may be left on their hands may prevent hospitals from taking them for treatment in the early stages when chronic illness might be prevented. Despite the shortage of beds many old people have to be taken to hospital or institution for purely domestic reasons rather than because of ill health. To keep sick old people from deteriorating into chronic invalids because of the lack of mental and physical stimulation of any kind is of the greatest importance. It is even more weakening for the elderly to remain in bed than for younger patients, owing to their lack of resilience.

SUITABLE FORMS OF ACTIVITY

From birth onwards exercise is necessary to health, and this still holds good in old age. It is far too easy, often with the encouragement of relatives, for an old person to get into the habit of spending much time in bed and the rest of the day sitting by the fire instead of making the effort to put on outdoor clothes and get going. I have rarely seen harm come from the daily walk, even for those in frail health, if they can manage it, and it is undoubtedly stimulating both to mind and body. Going up and down stairs in moderation is good exercise and is especially beneficial in keeping joints flexible. With children it is often easier to do the work than to allow them to help, as they would like to do, and the same thing applies to the old whether in their relatives' homes or in residential establishments: but it is undesirable.

Over-anxiety for the old may be as harmful as neglect. This is often so with old people living with their families. In the name of kindness they are gradually prevented from any activity or independence and this finally wears them down. I have several times met interesting examples of this.

Mrs. J was married to a man considerably younger than herself who waited on her hand and foot. She allowed him to do more and more—the cooking, the shopping, and the housework—while she became less and less active and simply sat about or lay in bed smoking cigarettes; she even reached the stage of incontinence through laziness. Then one day her husband had a seizure and was removed to hospital. Mrs. J was cared for by a middle-aged son for a time, but this situation became impossible and she was removed to a voluntary home. Re-education started at once and, at first, much against her wishes. She was encouraged to get up and walk about and even to help with minor household jobs. If she had an accident she was made to clear it up herself, and this quickly cured her of incontinence. She became in fact quite a normal old person. Her greatest pleasure was to go to hospital to see her husband and on one occasion I took her myself. When she reached the hospital and she got out of the car, she suddenly found she could hardly walk at all, and had to be more or less dragged in. It was clear that the old attitude was returning with the prospect of seeing her husband, and if he had come back to live with her, she would quickly have relapsed into her old habits.

This is an extreme case, but many old people can be reduced to invalidism if nothing whatever is expected of them.

NURSING OF THE AGED

One of the skills necessary in nursing old people is that of knowing when to leave them in bed, and when

---

* F. E. Williams' lecture for 1952, delivered before the Royal College of Physicians of London on July 15.

to encourage them to get up and then to move about and go out. The difference in will-power for recovery is always unpredictable. Desire for the adventure of living is easily lost, but can recover to a surprising extent in skilful hands. It depends largely on whether interests have been developed earlier in life. As one woman said, "I have never read a book because I have never had time, but I am told I have missed a rare treat!"

I remember one old woman of ninety who was sent to me by the milkman. He had found her sitting on the pavement tired out with searching for a room. No one would accept her as a tenant for she looked poor, dirty, and ill. She had been offered a place in an institution, but she had said that this was out of the question as she must be able to have access to a library and be able to read. She was found a single furnished room and here she lived for some years completely happy reading Milton, Byron, and Shakespeare, first with both eyes, then with one, and finally, when she became almost blind, she gave up her reading and died.

It is impossible to overemphasise the fact that the function of the hospitals is to cure illness and their equipment is not suited to any other purpose. When no further treatment is possible different conditions than those of the hospital ward are required. There must be some place for chronic patients where there is every incentive for the activities of which they are capable, and for encouragement to be up and about. There is no more dreary sight than rows of chronic sick beds. Prof. A. P. Thomson, of Birmingham, in his report on the *Care of the Chronic Sick*, writes:

> "My most vivid impression of the chronic ward of this hospital is an atmosphere of profound apathy. . . . The hospital treatment was surprisingly good . . . the words 'medical treatment' are used in the narrowest sense to signify therapeutic use of rest and drugs."

Most of the inmates of the chronic wards must be regarded as a sad inheritance of a long period of neglect. There are, of course, notable exceptions, but these words describe the lot of thousands of old people in all parts of the country.

It is essential that the most helpless of the chronic sick should be cared for permanently in some kind of hospital, but there is no reason why conditions in some hospital wards should be so deplorable. Years of lying in a ward sometimes amounts to actual cruelty; where, for instance, it is rarely possible to get out of doors, and where there are no decisions to be made, no responsibilities to be accepted. Life is regularised, movement limited to sitting on a chair beside a bed, attired in a dressing-gown, and possessions are almost non-existent. Unfortunately many hospitals have no provision for patients' clothes, even when they remain in hospital for many years. The effect is psychologically bad and not conducive to a return to ordinary living; also from the point of view of geriatric treatment there is little better gentle exercise than that of slowly dressing.

An old woman of my acquaintance suffering from rheumatoid arthritis lived alone upstairs. She managed two small flights of stairs and with a home help succeeded in keeping her home very well. Recently she went to hospital on account of digestive trouble. This quickly cleared up, but she was kept in bed and when sent home at the end of a few weeks she could do nothing for herself and became completely bedridden. Again, an elderly woman came to one of our homes suffering from rheumatoid arthritis. She had been in hospital for 3½ years and, although mentally alert, she had never been dressed, as she had no clothes in hospital, and had therefore never been out. She had most successfully learned to do absolutely nothing, and unfortunately had lost all power or incentive to help herself; she was greedy of one thing only, and that was attention by the nurses to her physical wants, and she assumed a garrulous, demanding attitude to anyone who would attend her.

POSSIBILITY OF BETTER CONDITIONS

There are residential homes where it has been shown that old people who have been rendered immobile by crippling diseases can still find much enjoyment of life. In one such home they are taken for bus-rides, even the very crippled, which resuscitates them more than any physic. They spend much of their time in the garden in summer and have their possessions round them at the cost of tidiness. They go to bed and get up when it suits them, and they are encouraged to occupy themselves in any way possible. All this, incidentally, costs only a third or less of a hospital bed. Although few of these patients can walk out in the road, they have a spirit of gaiety and happiness due to activity of mind even if not of body. A series of very small activities makes all the difference between complete lethargy and liveliness, but all such activities take time on the part of the attendants. Through the overemphasis of safety-first methods, old people are kept in bed for long periods for fear of falls or other accidents. This may be done to save possible censure of the hospital staffs, but it is at the expense of liberty and happiness.

The will to live is the strongest of all instincts and persists in old age. Old people rarely want to die even when life seems to have little to offer. Sometimes fear of death inclines an aged invalid to accept a life involving no sort of effort as the safest means of preserving it. Furthermore, when old persons with an income are cared for by the regional hospital board they contribute nothing for maintenance. Their income can be given to their relatives and this can continue for an unlimited period of time. A return to activity and the resulting transfer from a hospital bed to other accommodation may mean payment of the cost of maintenance. The improvement in health resulting from this change is consciously or unconsciously resisted both by the old people and their relatives. A heavy reward is paid for a continuance of infirmity.

Old people sleep much less at night than younger people and it is acute misery for many of them to lie in bed perhaps up to fifteen hours nightly, sleeping little, listening to the coughing and snoring of their fellows, and waiting for the coming day. Old people are extremely individualistic, and to have any rule by which they must all go to bed and get up at one set time cannot possibly be right. Incontinence alone should rarely be a reason for bedfastness. It may be easier for the nurses to keep them in bed, but it is wonderful how this disability can be managed by experienced and patient attendants. The treatment of incontinence is, indeed, a special science and it is a sign of failure on the part of the nurses when an active-minded patient is restricted to a chronic bed for this reason alone.

Extreme cleanliness and tidiness is of course essential in a surgical ward, but in the wards for the chronic sick the constant struggle for tidiness often results in unintentional but nevertheless cruel discipline. Probably the basis of the whole trouble is that old age and sickness have been for too long confused. Actual skilled nursing, though important, should not be the predominant feature in caring for the aged. Kindliness and resourcefulness should come first, the skilled nursing being reserved for those in real need of it.

The chief difficulty in employing untrained attendants for the chronic sick is their difficulty in lifting the more helpless patients. If they could be taught the best methods, the situation would be greatly eased, since in other respects they can give much of the care required.

Lack of possessions is a sore trial, and the care of even a small assortment of personal treasures gives occupation. Indeed in some cases of mental instability, the arranging and rearranging of possessions is the one steadying influence. I remember one old lady who was getting extremely vague about everything. She tidied her chest of drawers for many hours a day. When it was suggested that so much standing was bad for her and she was prevented from doing it, she became quite violent.

One of the causes of the liability to become bedfast fter arrival in hospital or home is the shock which old eople suffer from any sort of transference from one lace to another. We have observed that on arriving t a strange place this tendency to shock makes them eem much more incapable than they really are. Great atience is needed at this stage to make the change-over asy for them, and where this help is not given they may apidly break up altogether. This is not always due to a ack of desire for the change, for even when they have hosen this themselves they still seem to undergo mental isturbance for a time after arrival. In bringing people o our homes, we often advise them not to give up their previous dwelling until they have settled in. This gives hem the feeling that they have not completely cut away nd could, if necessary, still return to their old way of life. Even so we can rarely form any correct estimate of their condition for the first week or two.

With the old there is a special danger of paying too much attention to their physical ills and too little to their mental troubles. Actually disabled old people are still capable of considerable happiness where they are not in bondage to an exaggerated and soul-destroying emphasis on the need for cleanliness of the body and tidiness of surroundings. Mental deterioration is inevitable with unlimited and unoccupied leisure. Chronic inactivity of the mind is even more harmful than that of the body. It is as important to take early steps to prevent disease in the elderly as in any other section of the community although it may require more realisation of the close connection between ills of the mind and body. People are still expected to know by instinct how to look after their ageing relatives as they were once expected to know by instinct how to care for young children.

IMPORTANCE OF COÖPERATION

Since at present accommodation and service are insufficient, it is important for each district to take stock of its resources and use them to the best advantage. Many organisations are not fully used from lack of concerted effort, and because of the difficulties of getting the right people into the right places. Those who are not in need of hospital treatment help to fill the beds; old people die neglected at home because the hospitals and homes for the old have too many people in them who could live in their own homes if flatlets were available for them.

In one area which I know well a great deal of coöperation between all these forces has been achieved. Let us follow the fortunes of an imaginary old lady.

> She lives alone and is well known to the Old People's Welfare Committee who have helped her by arranging for meals to be brought to her, and giving useful advice and occasional help in cleaning. She has fallen ill and the doctor cannot get her a bed in hospital and she cannot afford help at night. However, the wheels get moving. In order to admit her to hospital, a convalescent old lady is moved out into a half-way house or convalescent home that has been set up by the King Edward's Hospital Fund; to vacate a bed there, an old lady is moved to a permanent voluntary home; and again in order to find room for her, the local voluntary housing association finds a furnished room or flatlet for an elderly woman who has improved in health and would like to live independently again.

This combined effort is much more effective than isolated action on the part of the hospital, home, or housing trust. The hospital will cease to be wary about taking a temporary patient nor will a home be afraid of taking a frail old lady with whom they might be left when she became bedridden. Not only do these particular organisations work together but they assist and are assisted by the welfare authorities, regional hospital board, and Assistance Board. Mutual goodwill and coöperation can save much effort.

Coöperation is greatly facilitated if, instead of setting up one large institution, several homes are grouped in such a way that residents of various mental and physical grades can be classified and placed together in most congenial surroundings. When there is a change in a patient's condition a shift from one home to another can be made without shock, since the management and atmosphere are so similar throughout and the residents are accustomed to sharing entertainments and excursions.

CONCLUSION

As much understanding and careful management is required for old people as is now afforded for infants and young children. Immense strides may be possible in the next few decades in the reduction of chronic sickness in old age, and these may be as dramatic as the recent drop in infant mortality. There are few more miserable sights than a ward of chronic sick invalids, and few more depressing occupations than their care. Robert Burton once said: "There is no greater cause of melancholy than idleness"; and we might add—no greater cause of ill health than melancholy.

CONVERSION OF TISSUE POLYSACCHARIDES TO AUTO-ANTIGENS BY GROUP-A BETA-HÆMOLYTIC STREPTOCOCCI

CANADIAN RED CROSS MEMORIAL HOSPITAL, TAPLOW, BUCKS

The ætiology of nephritis and the rheumatic diseases is still unknown, but many workers have suggested an antigen-antibody reaction as a possible mechanism (e.g., Klinge 1933, Rich and Gregory 1943, Hawn and Janeway 1947). Although lesions resembling in various degrees those of the corresponding human disease have been produced in laboratory animals by the injection of massive doses of foreign protein, this artificial procedure can only serve as a remote analogy to the sequence of events in the naturally occurring disease. It has seemed possible, however, to many investigators that specific antibody production in response to the individual's own tissues (acting as antigen) may be involved, rather than a non-specific antigen-antibody reaction induced by foreign material (Smadel 1936, Cavelti and Cavelti 1945). Unfortunately for this hypothesis, the experimental production of auto-antibodies has proved extremely difficult, although a-priori evidence of the possibility exists in the acquired hæmolytic diseases (Loutit and Mollison 1946).

In rheumatic fever (and to a lesser extent in nephritis) recent infections with hæmolytic streptococci are accepted as an essential ætiological factor. It has been suggested that the effect of these is to render the tissues auto-antigenic. The claim of Cavelti and Cavelti (1945) to have utilised this mechanism in the experimental production of nephritis and carditis has not, however, been confirmed (Humphrey 1948).

The classical work of Landsteiner (1945) has shown that the antigenicity of a protein may be profoundly altered by chemical combination with various non-protein substances (haptenes). Among the latter the polysaccharides are of outstanding importance in conferring specificity on bacterial antigens (Heidelberger and Avery 1923, 1924, Avery and Heidelberger 1923, 1925). A possible mechanism, therefore, for auto-antibody stimulation would be the combination between bacterial protein and tissue polysaccharide, acting as haptene. The work of Morgan and Partridge (1940) on the structure of the somatic antigen of *Shigella shigæ* has well shown that the protein moiety of this antigen can readily combine with polysaccharides such as agar and cherry gum to produce antigens capable of eliciting antibodies reacting specifically with the corresponding polysaccharide. It has been shown by Sordelli and Mayer (1931) that this property is by no means confined to dysentery organisms, and we have recently reported that hæmolytic streptococci are particularly active in endowing with antigenicity various polysaccharides of plant origin (Glynn and Holborow 1952). If it can be shown that these organisms can similarly react with polysaccharides of animal connective tissue, it is conceivable that the production of auto-antibodies to these tissue polysaccharides might occur in natural infections. Such a reaction could well underlie the pathogenesis of the group of diseases under discussion.

We report here results of such experiments, in which a preparation of chondroitin sulphate was used as tissue polysaccharide; a limited quantity only was available for this experiment, which was therefore restricted in scope. A note is also included on the production of nephritis in rats, using a tryptic digest of rat kidney as a source of kidney polysaccharide.

METHODS

Chondroitin sulphate * was prepared from stored wet human costal cartilage by the method of Einbinder and Schubert (1950) as a dry powder, readily soluble in saline solution.

Preparation of vaccines.—18-hour cultures in Todd Hewitt broth of a group-A type-4 strain of β-hæmolytic streptococcus were centrifuged, and vaccines prepared from the organisms washed twice in saline solution. The live cocci were suspended in a small volume of 1% chondroitin-sulphate solution in saline solution and kept at 37°C for an hour. They were next centrifuged, washed twice, and resuspended in saline solution to give an opacity equivalent to about 1000 million cocci per ml., and killed by heating at 56°C for thirty minutes. Control vaccines were prepared identically but without the chondroitin sulphate.

Immunising procedure.—Young cross-bred Dutch or Copenhagen rabbits, weighing 1·4–1·8 kg. and kept in individual cages on a mixed diet, were given intravenous injections of vaccine three times a week. On a dosage beginning with 0·5 ml. and increasing to 1·0 ml., and given a vaccine prepared in bulk at the outset of the experiment (schedule A), a high proportion of rabbits died or sickened after two or three doses. On a reduced dosage (starting with 0·1 ml. and gradually increasing to 1·0 ml.) and given freshly prepared vaccine for each injection (schedule B), the rabbits remained well during the initial stages of the immunising course.

Two Copenhagen rabbits received intracutaneous inoculations of chondroitin-treated vaccine in six daily doses of 0·1 ml. Three control rabbits received chondroitin-free vaccine, or chondroitin-sulphate solution only, intracutaneously.

Tests for precipitating antibody to chondroitin sulphate.—Sera were obtained from the rabbits at intervals and tested for precipitin reaction with 0·1% chondroitin-sulphate solution in saline solution. Ring tests, chondroitin solution being layered on serum, were unsatisfactory owing to the slow rate of appearance of precipitate, and precipitation was best observed in capillary tubes, as in the technique described by Swift et al. (1943) for streptococcal precipitin typing. Equal quantities of serum and chondroitin solution were drawn up into a capillary tube and incubated at 37°C for two hours. With positive sera maximal flocculation was observed after refrigeration at 4°C for up to forty-eight hours. Normal rabbit sera gave no trace of precipitation with the polysaccharide solution under these conditions.

Streptococcus-kidney-digest vaccine.—A tryptic digest of perfused rat kidney was prepared by the method of Cole et al. (1951) and a streptococcus-kidney-digest vaccine made in the same way as the vaccines described above.

RESULTS

Antigenicity of Chondroitin-sulphate Preparation Alone

A solution of chondroitin sulphate alone gave rise to no precipitins when injected intravenously—e.g., 60 mg. given over twelve days. Repeated intracutaneous injection over eight days (6 × 0·1 ml. of a 1% solution) did not cause skin sensitivity in two rabbits.

Antigenicity of Streptococcus Alone

Plain streptococcal vaccine gave rise to no chondroitin-precipitating antibody in the three rabbits immunised.

Antigenicity of Streptococcus-chondroitin Vaccine

Intravenous immunisation.—Six rabbits received intravenous streptococcus-chondroitin vaccine; four according to schedule A, and two according to schedule B. The sera obtained from these rabbits after immunisation all gave precipitation with chondroitin solution, varying from a trace to a ++ reaction (see table). One of these rabbits developed a limp in the left hind leg after fourteen days and was killed on the sixteenth day. Its serum gave a relatively strong precipitin reaction with chondroitin-sulphate solution. Post mortem the left knee-joint showed acute inflammation but was sterile on culture. The synovial membrane was œdematous and injected, and there was much hyperæmia round the articular margins. Another rabbit showed no clinical symptoms but died on the twenty-third day of schedule B. Serum obtained at this time precipitated strongly with chondroitin-sulphate solution, and post mortem both knee-joints showed much œdema and inflammation of the synovial membrane. As shown in the table, histological evidence of arthritis was obtained in five of the six rabbits receiving the streptococcal-chondroitin vaccine. In one this consisted of a slight infiltration with poly-

morphs; in two others there was considerable hyperæmia, with polymorph infiltration; in the fourth the inflammation was intense and acute; and in the fifth it was severe, but polymorphs were few, the predominant cells being lymphocytes and plasma cells forming well-marked perivascular aggregations. Cultures taken from all the joints examined were invariably sterile. No comparable degree of inflammation was found in any of the controls; in one rabbit only a slight polymorph infiltration was present.

Intracutaneous inoculations.—Of the two pairs of rabbits inoculated intracutaneously one member of each pair received streptococcus-chondroitin vaccine and the other received the streptococcus alone. Six daily injections were given in the skin of the flank, and skin tests with 0·1 ml. of 1/1000 chondroitin sulphate were made after an interval of five days. Considerable skin sensitivity to chondroitin was elicited in the rabbits receiving streptococcus-chondroitin vaccine; negative results were obtained with the rabbits receiving streptococcus only. The positive skin reaction obtained was of the delayed type, appearing at about six hours, and maximal at twenty-four to thirty-six hours, taking two days to fade.

Experiments with Rat-kidney Digest

A rabbit antiserum to the streptococcus-kidney-digest vaccine was obtained, which when given intravenously to rats gave rise in twenty-four hours to gross albuminuria and to glomerular lesions in the kidney comparable to those induced in a parallel experiment by nephrotoxic serum (Smadel 1936). Normal rabbit serum or plain antistreptococcal rabbit serum produced no lesions or albuminuria.

DISCUSSION

It is evident from these results that the production of antibodies to polysaccharides of animal origin can be induced in the same way as those previously obtained against polysaccharides of plant origin. We cannot regard the haptene in these experiments as strictly autogenous, since the chondroitin was obtained from human cartilage; but there is little evidence that the composition of this material varies from species to species. It will, of course, be necessary in repeating these experiments to use chondroitin prepared from cartilage of the homologous species. A point of great interest relates to the extremely minute quantity of polysaccharide necessary to impart its own immunological specificity to the streptococcus. For example, with electrophoretic methods capable of detecting a few microgrammes of galactose, it has been impossible to detect even a trace in 2 mg. of dried cocci, previously treated with agar, although vaccines prepared from these readily elicited antibody to agar. Figures for the purity of the chondroitin sulphate are unfortunately not available; its N content, however, was only 2·2–2·4%. Since chondroitin sulphate has an N content of less than 3%, other protein could not have been present in more than traces. This is confirmed by the absence of antigenicity of the polysaccharide solution alone.

Of the six rabbits injected with the streptococcus-chondroitin the two showing strongest serum precipitation showed also the most conspicuous joint lesions. Less severe lesions were also present in two of the rabbits showing less precipitation. This does not necessarily imply that the lesions are due to the antibodies responsible for the precipitation reaction; it is quite conceivable that, if antibodies are responsible for the lesions, they belong to the non-precipitating type. It does, however, suggest that lesions are most likely to occur in those animals with the most responsive antibody mechanisms.

As already mentioned, the scope of these experiments has been limited by the small quantity of animal polysaccharides available in a relatively pure and undegraded state, and we hope to confirm and extend these observations with more polysaccharide material.

SUMMARY

A vaccine prepared from group-A β-hæmolytic streptococci in the presence of chondroitin sulphate gave rise to rabbit antisera precipitating with this polysaccharide.

Of six rabbits immunised with such a vaccine five showed macroscopical and/or microscopical evidence of joint lesions. Control rabbits receiving either streptococci or polysaccharide alone showed no joint lesions apart from an occasional polymorph in the synovial membrane.

We acknowledge with pleasure the advice and interest of Dr. E. G. L. Bywaters and the biochemical advice of Dr. R. Consden.

DEFORMING FACTORS IN THE EARLY STAGE OF POLIOMYELITIS

G. P. MITCHELL
M.C., M.B. Aberd., F.R.C.S.E.
SENIOR REGISTRAR, WINGFIELD-MORRIS ORTHOPÆDIC HOSPITAL, OXFORD

From the Nuffield Orthopædic Centre, Oxford

THE term "muscle spasm" has often been used to describe various types of muscle dysfunction in poliomyelitis, but there does not seem to be any general agreement on its definition and cause.

Pohl and Kenny (1943) consider muscle spasm to be a decisive factor in the course of poliomyelitis. Pollock et al. (1949), on the other hand, deny the existence of muscular spasm, which they define as a state of sustained involuntary tetanic contraction of muscle—a definition with which I agree. Excluding the types of muscular spasm attributed to the meningeal reaction, they found no evidence of true spasm in patients studied during the first ten days of poliomyelitis.

Because of the existing controversy I have tried here to describe more accurately the various clinical findings which are sometimes collectively described as spasm, and to discuss their ætiology.

DEFORMING FACTORS

In patients who have had little or no treatment in the early months of poliomyelitis, deformities are occasionally found which seem to be due to abnormal overaction of unaffected or mildly paralysed muscle groups. It is therefore essential to study the factors concerned in the limitation of passive mobility in the first few weeks of the disease. Deformities appearing later, which are due to neglect of a paralysed limb or to the influence of simple muscle imbalance on growth, will not be discussed.

For the present purpose the term "deforming factors" is used to describe any conditions which interfere with the passive mobility of the limbs in the early stage of poliomyelitis. The observations are based on the study of over 100 cases examined during the isolation-hospital stage and subsequently in the orthopædic hospital.

Deforming factors appear to be manifested in three ways: (1) limitation of straight leg raising; (2) limitation of shoulder abduction beyond 80°; and (3) muscle resistance to stretch. These conditions do not all necessarily proceed to established deformities if untreated.

Limitation of Straight Leg Raising

The limitation of straight leg raising referred to here is that persisting after the initial acute meningeal reaction has subsided. When present to any great extent it persisted for many weeks and could not be completely abolished by treatment in the early stage, but improved in the later stages on mobilisation of the patient, particularly by walking and sitting.

In severe cases pain was produced when the leg was raised to an angle of 30°, accompanied by painful resistance to stretch of the hamstrings when these muscles were not paralysed. Where the muscle on one leg was considerably weaker than that on the other, there was only a minor difference in the angle obtained. Even when complete paralysis affected the hip and leg, straight leg raising was limited by pain often to 30° unaccompanied by muscle resistance.

The limitation of straight leg raising was always bilateral and not necessarily proportional to the degree of paresis, but was not present unless there was some paralysis of the leg.

In these patients the hip-joints were mobile and could be flexed to over 90°. All the patients had lumbar pain in the early stages, and several had neck stiffness, but severe degrees of neck stiffness were often unaccompanied by any limitation of straight leg raising.

Limitation of Shoulder Abduction

This was an outstanding feature in the few patients presenting severe degrees of resistance to muscle stretch in the biceps and shoulder adductor muscles. It was also present in patients with respiratory weakness, when the pectorals were used as accessory muscles of respiration.

Limitation of shoulder abduction persisting after the initial meningeal phase was found in many patients with paralysis affecting the arms. Pain was produced on abduction beyond 80°, accompanied by strong resistance in the shoulder adductor muscles when these were active. It was only seen where the arm or the trunk was affected, and was bilateral in severe cases. Neck stiffness was a feature of the febrile stage in these patients. When the shoulder was abducted to a few degrees below the pain-producing angle, pain could be produced by lateral flexion of the neck to the opposite side.

This limitation of shoulder abduction was more easily overcome than the limitation of straight leg raising.

Muscle Resistance to Stretch

A state of sustained tone or "spasm" in the muscles of the neck and back was often observed during the meningeal reaction of the first few days in both paralytic and non-paralytic cases. This sustained tone disappeared as the fever subsided, but was sometimes followed by muscle resistance to stretch, which developed on attempted flexion of the spine. This muscle resistance gradually subsided over a longer period.

As has been mentioned, muscle resistance to stretch developed in the hamstrings during the straight-leg-raising test and in the shoulder adductor muscles during the shoulder-abduction test. This resistance was only present when the muscle was able to contract, and it was therefore considered to be a secondary phenomenon.

In a few patients considerable muscle resistance to stretch was noticed in certain muscles, particularly the biceps, when the elbow was held in a flexed position and any attempt at extension initiated contraction at about 90°. This was considered to have a more complex ætiology than the muscle resistance mentioned in the preceding paragraphs, and was considered to be a significant deforming factor if untreated. For this reason it will be discussed under a separate heading.

This type of increase in muscle tone in the extremities was an infrequent finding. In 100 patients treated from the onset by the methods in use at Oxford and previously described by me (Mitchell 1952), 4 patients showed significant muscle resistance to stretch of a degree likely to persist if untreated. The biceps muscle was affected in 3 cases, and the calf muscles in 1 case; 2 other patients developed biceps resistance during the respiratory stage of the illness. No example of true spasticity was found; clonus and increased tendon-reflexes were not obtained. Observation at the onset did not reveal any muscle contraction in the limbs when at rest; this state was brought on by any attempt to stretch the muscle and was accompanied by pain. The term "muscle resistance to stretch" is preferred to the more common term "spasm" in describing the muscle dysfunction.

The muscles usually affected were the elbow flexors, adductors of the shoulder, and calf muscles. If such a muscle is allowed to remain in a position of advantage, the temporary state of resistance by contraction is gradually superseded by shortening, the muscle being felt as a tight cord under general anæsthesia in contrast to the relaxation obtained in the early stage.

CLINICAL OBSERVATIONS

In an attempt to explain these changes in the cases we have examined, the clinical features only will be discussed, no necropsy material being available.

Limitation of Straight Leg Raising

As has been mentioned, in these cases the hip-joints were mobile and could be exonerated. The degree of muscle power present did not materially affect the angle of straight leg raising obtained, which was severely limited even when muscle power was minimal or absent. The limitation was caused by muscle resistance to stretch plus pain where muscle power was good, and by pain alone when muscle power was absent. Intravenous thiopentone was given in 1 case with persistent limitation of straight leg raising six weeks after the onset. Under anæsthesia the straight-leg-raising angle was increased from 30° to 90°, showing that permanent shortening of the muscle had not taken place. It was not thought justifiable to paralyse the muscle, since Schlesinger (1951) found that limitation and pain persisted even with muscles rendered atonic with intravenous mephenesin. It is unlikely that brain-stem lesions were responsible for the limitation where muscle power was unequal or absent. Muscle resistance to stretch, when present, did not correspond to the spasticity seen in proved traumatic brain-stem lesions. Lasègue's sign was positive in all cases where limitation was severe.

The most likely site of lesions causing pain and limitation on attempted straight leg raising was considered to be in the region of the meninges and dorsal roots. The backache and limb pains of the early stage were considered attributable to inflammatory lesions at this site. The clinical picture in the early stage closely resembles certain cases of intervertebral-disc protrusion.

Limitation of Shoulder Abduction

Limitation of shoulder abduction over 80° was seen less often than the leg limitation, but certain features were similar. It was always accompanied by some degree of upper-limb paralysis—the abduction limit was caused by pain where muscles were paralysed, and by pain plus muscle resistance to stretch where power was present. Possibly the limitation and neck stiffness could also be due to changes in the region of the dorsal roots and meninges.

uscle Resistance to Stretch

This was only a transient complication when cases ere treated from the onset by rest, sedation, gentle assive movements, selective positioning, and splintage. dvanced cases were seen where inadequate early treatent had been given. The muscle resistance was usually lateral and occurred in slightly affected or apparently ormal muscles. The flexor adductor groups of the arm ere more commonly affected, particularly the biceps, ny attempt to extend the elbow being opposed by rong contractions. Patients with much biceps resistance ossessed highly emotional temperaments. Pain was a oticeable feature in all the cases.

Several factors were considered to contribute to the ate of muscle resistance to stretch as seen in these atients: (1) incoördination of muscle action caused by nternuncial lesions; (2) overaction of muscle, either eliberate or from emotional tension; and (3) limb pain.

(1) *Incoördination of muscle action* in the early stage as found in many patients. Kabat and Knapp (1944) ttribute this to the internuncial lesions.

(2) *Overaction of muscle.*—Continued overaction of a tronger over a weaker muscle could cause fatigue and ggravate pain; if untreated, this might progress to hortening and resistance to stretch of the stronger muscle.

An example of deliberate overaction of partially affected muscles progressing to actual muscle shortening was found in . female patient with paralysis of all limbs and trunk. While n the respirator she developed considerable limitation of houlder abduction owing to the continued use of the pectoral nd latissimus dorsi muscles as accessory muscles of respiraion. During her periods out of the respirator adjustable wooden wedges were inserted between arm and thorax and adjusted to the greatest comfortable abduction. By this neans abduction was gradually improved and eventually a useful range obtained without interfering with the accessory action of the pectoral muscles.

Disproportion in strength between protagonists and antagonists does not necessarily produce deformity; therefore aggravating factors must be present: either deliberate and continued overaction as in the case described, or emotional overaction from prolonged tension in the muscle of a highly emotional patient, when a strong biceps predominates and unrestricted use of the limb in the supine position is allowed. The prevention and ease of correction of such a flexion deformity in the early stage suggests that functional overaction may play some part in its production, perhaps by aggravating the dysfunction produced by pain and incoördination.

A typical example of biceps resistance was in an adult male R.A.M.C. orderly, who was very concerned about the outcome of the disease. He developed biceps resistance on passive extension of the elbow beyond 90°. After a few days' treatment, by engaging him in conversation, the elbow could be passively extended. On drawing his attention to the elbow, however, the muscle resistance reappeared. Later the resistance completely disappeared, but it is of interest, in connection with the other phenomena, that he had pain on abducting the shoulders beyond 80°, and that straight leg raising was limited to 30°, with a positive Lasègue sign. This patient also had a partial lower-limb paresis.

Deformities due to hysterical contracture of muscle were seen in a female patient admitted six weeks after an illness originally diagnosed as poliomyelitis. It was stated that she had developed complete flaccid paralysis of the left arm and leg, but that subsequently "muscular spasm" had appeared and produced deformities. On admission it was noted that an increase in tone and resistance to stretch was present in both flexor and extensor muscles of the left arm and leg. The elbow was maintained in acute flexion and the hand in the "main d'accoucheur" position. The knee was held in full extension and the foot in equinovarus. Tendon-reflexes were increased n the leg, and Babinski's sign was negative.

(3) *Pain* was present in all the cases of muscle resistance o stretch. After generalised limb pains had subsided, pain occurred only on attempted active or passive movement of the limb. Muscle biopsies in man have failed to show any significant pathological change in the muscles (Clawson 1948, Jungeblut 1950). The site of pain must therefore be between the myoneural junction and the dorsal roots. Inflammatory changes have been found at necropsy in the region of the dorsal roots and meninges (Bodian 1948). Possibly the increased resistance to stretch in muscles such as the upper-limb flexor adductor groups could be an exaggerated muscle guarding in response to pain originating in the dorsal roots or meninges, contributory factors being incoördination resulting from internuncial neurone lesions and emotional overactivity of muscle.

Recently two patients were seen who demonstrated mild muscle-movement resistance of special interest and similarity. Both were healthy adult males of stable mental make-up. The muscle resistance was of minor degree and only present for a few days, after which it completely disappeared. In both cases there was some connection with movements of the cervical spine and the production of muscle resistance.

The first patient on examination showed a mild tendency to biceps stretch resistance which was easily overcome. The shoulder was then passively abducted to 100°, when the patient complained of pain radiating down the forearm, and the biceps contracted, resisting full extension by 30°. When the arm was brought down to the side, the pain and biceps contraction disappeared. When the arm was brought down to just below the pain-producing angle, the pain could be reproduced by lateral flexion of the neck towards the opposite side—this latter sign has since been found in several patients with limitation of upper-limb abduction but was not looked for in previous cases.

The second patient, who was reported as tending to develop deformities, had been propped up in bed with pillows because of respiratory difficulty. He had severe neck stiffness, and overaction of the biceps and shoulder adductors maintained his arms flexed and adducted. When he was placed supine, all the resistance in the muscles disappeared, allowing a full range of passive movements. The neck stiffness disappeared the following week.

CONCLUSIONS

The limitation of straight leg raising and shoulder abduction is considered to be due to pain arising from residual inflammatory changes in the region of the dorsal roots or meninges. In these cases muscle resistance to stretch is guarding in nature.

The greater resistance to stretch found occasionally in muscles such as the biceps cannot be explained by a guarding action alone. Muscle incoördination plus emotional overactivity of a strong or relatively unaffected muscle over a weaker affected muscle may exaggerate the underlying guarding mechanism.

These conclusions have been reached from clinical observations, and I agree with the opinion of Magoun and Rhines (1947) that "further investigation of the pathophysiology of spasm in poliomyelitis would appear necessary before it can be stated definitely to be either an exaggerated stretch reflex or tension maintained reflexly or voluntarily in response to pain or to have some as yet unanticipated etiology."

SUMMARY

Deforming factors appearing in the early stage of poliomyelitis are defined as: (1) limitation of straight leg raising; (2) limitation of shoulder abduction; and (3) muscle resistance to stretch.

Clinical observations are reported which suggest that pain is the main cause of the onset of deforming tendencies in the early stage. Resistance to stretch is guarding in nature. Incoördination and emotional overactivity or tension in a muscle may play a part in the production of the more severe deformities.

I am indebted to the staffs of the Slade Isolation Hospital, Oxford, the Abingdon Isolation Hospital, and the Wingfield-

Morris Orthopædic Hospital for their help and encouragement. I wish to express my appreciation to Prof. J. Trueta and Mr. J. C. Scott for criticism and advice in the preparation of this paper.

SALT-LOSING NEPHRITIS

C. L. JOINER
M.D. Lond., M.R.C.P.
ASSISTANT, DEPARTMENT OF MEDICINE, GUY'S HOSPITAL MEDICAL SCHOOL, LONDON

M. G. THORNE
M.B. Camb., M.R.C.P.
MEDICAL REGISTRAR, GUY'S HOSPITAL, LONDON

THE importance of maintaining the sodium and chloride reserves of the body and of recognising the clinical features resulting from the deprivation of salt as opposed to water was emphasised by McCance (1936) and again by Marriott (1947). Marriott pointed out that sodium depletion presented an easily recognisable syndrome, whose prominent features are weakness, fatigue, giddiness, fainting, muscular cramps, anorexia, nausea and vomiting, and, later, hypotension and coma.

Sodium occurs so plentifully and widely that inadequacy is seldom the result of a simple deficiency of intake, unless it is due to a salt-free diet too strictly prescribed or too conscientiously followed and aggravated perhaps by the sodium diuresis induced by mercurial drugs (Soloff and Zatuchni 1949). A more common cause of a low sodium state is excessive loss, either from the skin by sweating or from the alimentary tract by vomiting, diarrhœa, or fistulæ. Finally, too much sodium and chloride may be excreted by the kidneys. This loss may be the result of functional changes in the renal tubules, when a deficiency of adrenal cortical hormones induces failure of tubular absorption, as in Addison's disease; or when, as in certain chronic illnesses, in the absence of any apparent renal lesion the ability to retain sodium and chloride is impaired (Winkler and Crankshaw 1938). It is evident also that an addisonian picture could, in theory, result from disease of the renal tubules. Although Peters et al. (1929) described excessive urinary loss of chlorides in certain cases of nephritis, Thorn et al. (1944) were the first to demonstrate what they called "salt-losing nephritis" as a clear clinical picture.

These workers described two cases, both young adults without previous history of renal disease. One was admitted to hospital in a drowsy state, collapsed (blood-pressure 64/46 mm. Hg), vomiting, and suffering from cramps; the other was nearly comatose (blood-pressure 35/0 mm. Hg). In both cases the sodium and chloride levels were grossly lowered in the serum and normal in the urine. Neither patient was pigmented, but adrenal cortical failure was diagnosed because no cells or casts were found in the urine of either, and only a trace of albumin in one. Treatment with large doses of deoxycortone acetate and adrenal cortical extract was ineffective, however, and only the administration of sodium chloride corrected the addisonian symptoms and raised the blood-pressure. The salt-losing tendency appeared to be a transient phase in the disease, and later it ceased, the patients finally succumbing in 2 and $4^1/_2$ years from uræmia and hypertensive heart-failure. At necropsy the kidneys in both cases were reported to show the changes of chronic nephritis, while the adrenals were quite normal.

Only four other cases of salt-losing nephritis have been described (de la Balze and Oñátivia 1947, Borst 1950, Sawyer and Solez 1949, and Nussbaum et al. 1952). In addition Rosenheim (1951) referred to this disorder and briefly cited another possible case. Nevertheless it is possible that similar cases have been reported previously as examples of Addison's disease with hypertension or Addison's disease complicated by chronic nephritis, particularly when such diagnoses have not been confirmed at necropsy. We acknowledge the undoubted authenticity of certain of these cases of combined renal and adrenal failure, however (Ravreby and Sawyer 1948).

We have found no original descriptions of this condition in the literature of this country, but it has been the subject of an annotation (*Lancet* 1952). In presenting a further three cases, therefore, we hope to draw attention to an important differential diagnosis of Addison's disease and one whose treatment should, in most cases, be at least temporarily rewarding. Case 1 reported here cannot be considered to be established beyond doubt and is presented as being of historical interest, for, although the disease was not proved to be a salt-losing one, the account of the clinical and pathological findings accord well with the original description of Thorn et al. (1944). All three cases were investigated and treated at Guy's Hospital.

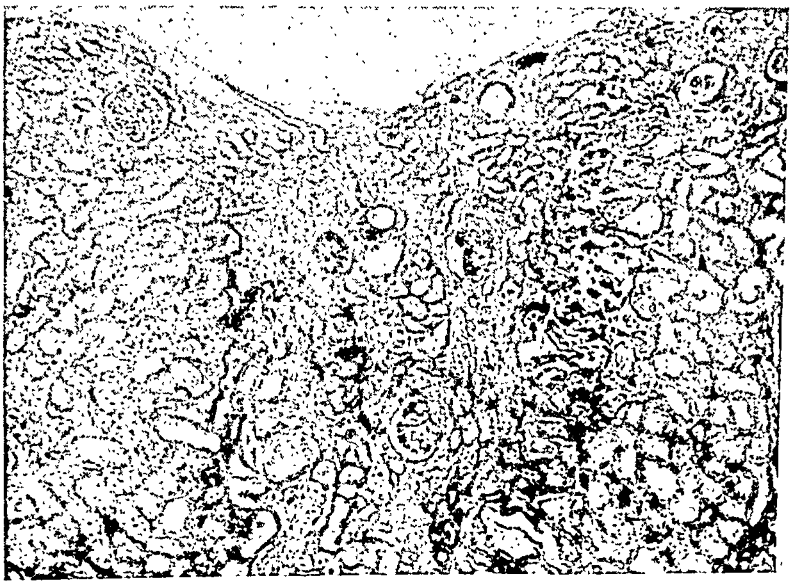

Fig. 1—Depressed cortical scar, tubular dilatation, and glomerular sclerosis of chronic pyelonephritis (case 1). (Van Giesen × 26.)

CASE-RECORDS

Case 1.—A girl, aged 20, was admitted on June 30, 1930, under the care of *Dr. John Ryle*. She complained of being easily tired, "slack," weak, and irritable since an attack of influenza two years previously. She had noticed bronzing of the skin for about a year, and amenorrhœa for 4 months. Until the age of 17 she had had nocturnal enuresis, and since then had had considerable frequency by day and night. At the age of 9 months she had had pneumonia, and at the age of 13 months scarlet fever and diphtheria. She had had other childhood ailments, including two operations on tonsils and adenoids. One sister had recently died from tuberculosis.

On examination she weighed 6 st. $4^1/_2$ lb. and appeared somewhat younger than her

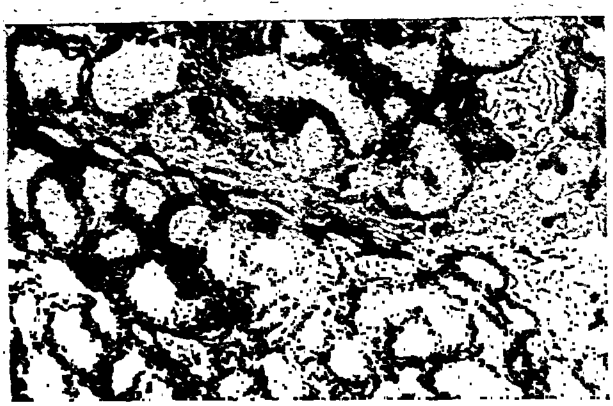

Fig. 2—Calcification of basement membrane of hypertrophied and dilated tubules (case 1). (Von Kossa × 74.)

years. Her skin was "bronzed," and her nipples were deeply pigmented. There was additional darkness over pressure points, and some small pigmented spots were seen in her mouth. Her blood-pressure was 100/70 mm. Hg., but no abnormality was detected in any other system. Her urine, sp. gr. 1·016, showed a trace of albumin. A blood-count showed Hb 7·2 g. per 100 ml., red cells 2,650,000 per c.mm., colour-index 0·92, and white cells normal. A test-meal was likewise normal. Radiography of the chest showed infiltration at the right apex. Dr. Ryle thought her condition most like that seen in Addison's disease.

Progress.—The patient rapidly deteriorated, and by July 9 was much worse, complaining of great lassitude and malaise, and her blood-pressure was 79/57 mm. Hg. On July 10 she was almost comatose, her reflexes being only just obtainable, and her pupils reacting poorly to light. Her blood-pressure then was 69/48 mm. Hg. By the afternoon she became unconscious, her pupils ceased to react to light, and shortly after this she died.

Necropsy findings.—Both adrenal glands were large and completely healthy. The kidneys were small (18 g. and 31 g.) and the capsules stripped easily, showing a mottled surface with some depressed scars. Section showed that the cortex was narrowed to 9–10 mm., and the corticomedullary junction ill differentiated. The skull was thickened and soft, resembling that seen in Paget's disease. Some tuberculous infiltration was found at the apex of the right lung. The other organs were normal, the parathyroid glands not being noted to be enlarged. On histological examination (Dr. J. B. Enticknap) the kidney changes were seen to be those of healed pyelonephritis (fig. 1), with evidence of a recent exacerbation. Calcification was seen in the tubules (fig. 2). The adrenal glands were of normal structure.

Case 2.—A man, aged 27, was admitted on July 27, 1951, with several weeks' history of weakness and tiredness and about 6 hours' history of pain in the left loin and inability to micturate. His family history was irrelevant. At the age of 18 months he had a tuberculous gland excised from his neck. At the age of 20 years his right kidney was found to be tuberculous and was subsequently removed surgically. At that time his blood-pressure was 150/90 mm. Hg and some impairment of renal function was noticed even postoperatively, the blood-urea remaining raised at 48 mg. per 100 ml. in July, 1945, and 60 mg. in February, 1946. He continued to pass tubercle bacilli in his urine. In 1948, at the age of 25, miliary tuberculosis of the lungs was discovered and treated with streptomycin and rest, with good result, but the blood-urea level reached 200 mg. per 100 ml. at this period. There was a decline from this high level, but shortly before admission to hospital in 1951 it still stood at 120 mg.

On examination the patient was thin but of good colour. His blood-pressure was 115/80 mm. Hg, and the only significant physical abnormalities detected were pyrexia (103°F), pulse-rate 100, and tenderness on palpation of the left loin. His urine, however, contained protein 2 g. per litre besides pus cells and acid-fast bacilli.

Progress.—The pain in the loin subsided within a few hours, and the patient micturated freely. Within 3 days his temperature had fallen to normal, but a week after his admission there was a bout of anuria lasting nearly 24 hours. Even before this his general condition started to deteriorate. Cramps developed in his legs and hands, his appetite was poor, and he was weak, listless, and at times faint. His blood-pressure dropped but did not reach the levels seen in addisonian crisis, the systolic pressure never falling below 100 mm. Hg. Estimations of the serum-electrolytes now revealed a gross depletion of sodium, at 266 mg. per 100 ml. (115 m.eq. per litre), and of chlorides at 396 mg. per 100 ml. (114 m.eq. per litre), while the blood-urea level was considerably raised. Although the tongue and skin were dry and he vomited occasionally, he continued to pass considerable quantities of urine of a very low specific gravity, which nevertheless contained relatively large quantities of sodium chloride (see table). Treatment with sodium chloride by mouth was started, and later, because he did not tolerate this well, large quantites of physiological saline solution were given per rectum and intravenously. On the 14th day after admission, the serum-sodium level still being grossly depressed, the patient was given intramuscular injections of 10 mg. of deoxycortone acetate daily, but without clinical or biochemical improvement (see table). The renal function steadily deteriorated until on the 25th day the blood-urea level was 330 mg. per 100 ml. and the blood-uric-acid 17 mg. per 100 ml. The patient died in coma 31 days after admission.

Necropsy findings (Dr. D. H. Osborne).—The body was sparsely covered, with little subcutaneous fat. The heart was not enlarged, weighing 350 g. In the apices of both lungs were small areas of caseation surrounded by scar tissue, the remainder of both lungs being normal. The alimentary system was normal except for a suppurative swelling of the left parotid gland. The left kidney weighed 232 g., and several yellowish-white areas bulged through the capsule. On section a considerable amount of renal parenchyma was found to have become caseating masses, some of which communicated with the pelvis. The intervening tissue was mottled by more recent tuberculous lesions. The pelvis and ureter were moderately dilated and both were inflamed. The ureter was thickened and in its lower third would just admit a probe. The bladder showed slight congestion only, and the prostate and seminal vesicles showed evidence of tuberculosis. The adrenal glands were normal, and no abnormality was seen in the brain.

BIOCHEMICAL FINDINGS IN CASE 2

—	Aug. 3, 1951	Aug. 7, 1951	Aug. 23, 1951	Aug. 27, 1951
Serum-sodium (mg. per 100 ml.)	266 (*115*)	269 (*116*)	283 (*124*)	253 (*110*)
Serum-potassium (mg. per 100 ml.)	16 (*4·1*)	16 (*4·1*)	15·3 (*3·9*)	22·5 (*5·8*)
Serum-chloride (mg. per 100 ml.)	396 (*114*)	359 (*102*)	435 (*112*)	370 (*106*)
Plasma-bicarbonate (vols. per 100 ml.)	57·6 (*26*)	63·6 (*28·8*)	48·1 (*21·8*)	41·3 (*18·6*)
Blood-urea (mg. per 100 ml.)	147	150	126	330
Uric acid (mg. per 100 ml.)	..	..	..	17
Urine sp. gr.	1003	1004	1009	..
Urine sodium chloride content (mg. per 100 ml.)	..	272	212	..

Figures in parentheses represent m.eq. per litre.

Histological examination of the kidney showed widespread caseous tuberculosis (fig. 3) and in the areas not so affected changes that probably represent antecedent healed pyogenic pyelonephritis (fig. 4).

Case 3.—A boy, aged 18, was admitted in April, 1951, with a month's history of generalised cramps, weakness, and unsteadiness, and several months' history of mottled pigmentation of the face. There was no relevant family history, and he had worked as a farm labourer since the age of 14. He had always been very fit until the age of 16, when he had an attack of tonsillitis, followed by puffiness of the eyes and headaches. He first noted cramps soon after this illness. They were confined to his calves, and occurred after exercise and at night. He had always tanned easily in the summer, but the tan that he acquired in the summer of 1950 faded very slowly, leaving brown blotches on his face throughout the winter of

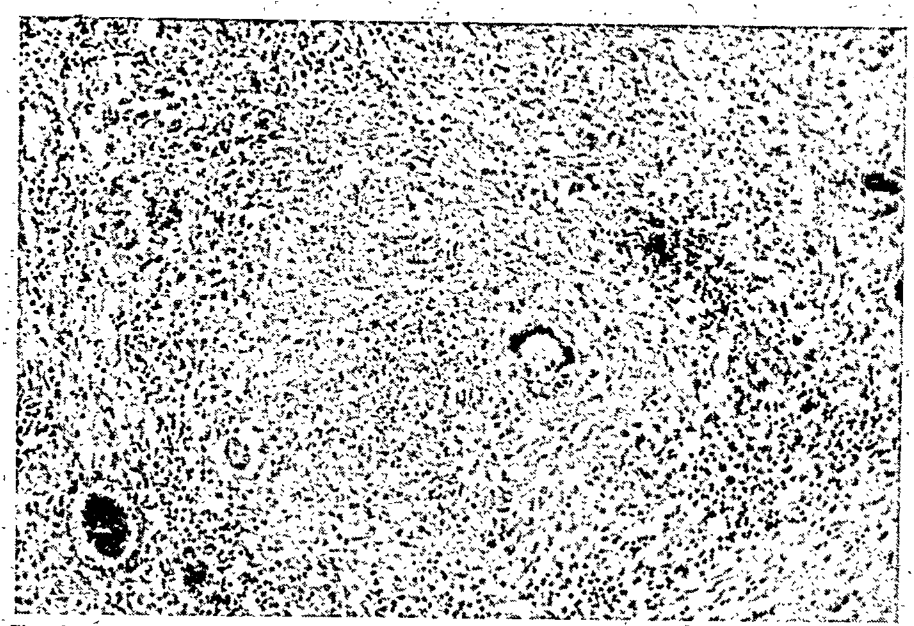

Fig. 3—Tuberculous granulation tissue, caseation, and interstitial inflammation (case 2). (Hæmatoxylin and eosin × 174.)

1950–51. In March, 1951, he noticed that he was rapidly becoming tired and breathless and had palpitations while doing the work to which he was accustomed. He also developed cramps of the hands and feet, and some shakiness. On one occasion he fainted. He was seen by his family doctor, who prescribed sodium chloride 16 g. daily by mouth, after which the cramps and unsteadiness were much improved, although he still felt weak and listless.

On examination patches of brown pigmentation were seen over his face and arms, but not on his buccal mucosa. Muscular twitching was noted during the examination. His blood-pressure was 140/65 mm. Hg, and his heart was not enlarged. All his reflexes were very brisk. His urine was of low specific gravity, seven specimens being below 1·010, and contained 2 g. of protein per litre. No formed elements were seen.

Treatment and progress.—It was thought that the diagnosis lay between Addison's disease and chronic nephritis, and the extra salt which had been prescribed was stopped for an observation period. He was given a normal diet, but with no added salt, and after 8 days the serum-sodium level had fallen to 302 mg. per 100 ml. (131 m.eq. per litre). On the 10th day he complained of weakness and nausea, and later began to vomit. His blood-pressure fell to 80/50 mm. Hg, but he rapidly improved when given salt by mouth. He continued to take sodium chloride 4 g. four times daily throughout his stay in hospital.

Investigations.—The blood-urea level was 205 mg. per 100 ml.; the blood-sugar 100 mg. per 100 ml.; the alkali reserve 26·2 vols. per 100 ml. (11·8 m.eq. per litre); the serum-calcium 8 mg. per 100 ml. (4 m.eq. per litre); the serum-phosphate 4 mg. per 100 ml. (1·25 m.eq. per litre); and the 17-ketosteroid excretion 7·95 mg. in 24 hours. After 10 days on 16 g. of salt daily, the serum-sodium level was 357 mg. per 100 ml. (156 m.eq. per litre) and the serum-chloride 367 mg. per 100 ml. (104 m.eq. per litre).

Discharge.—It was felt that the probable diagnosis was salt-losing nephritis, and that in view of the acidosis, and their response to salt, the cramps were due to the lack of sodium chloride rather than calcium. The patient was discharged, and recommended to continue to take 16 g. of salt daily.

Follow-up.—After his discharge he attended as an out-patient twice—in June, 1951, when he seemed in excellent health, and in January, 1952, when he said that he felt very well but had reduced his extra salt intake to 8 g. daily on advice from his doctor, who had noticed slight œdema of his ankles. He appeared much less pigmented than before, and his blood-pressure was 160/120 mm. Hg. The serum-sodium level was 350 mg. per 100 ml. (152 m.eq. per litre); the serum-chloride 340 mg. per 100 ml. (96 m.eq. per litre); the alkali reserve 42·4 vols. per 100 ml. (19·1 m.eq. per litre); the serum-potassium 19 mg. per 100 ml. (5 m.eq. per litre); and the blood-urea 110 mg. per 100 ml. The urine, sp. gr. 1·010, contained protein.

Readmission.—The patient was readmitted on March 16, 1952, having felt quite well until the end of February, 1952, when he noticed that his legs had become swollen up to the thighs: 2 days before admission he had developed a headache and vomiting.

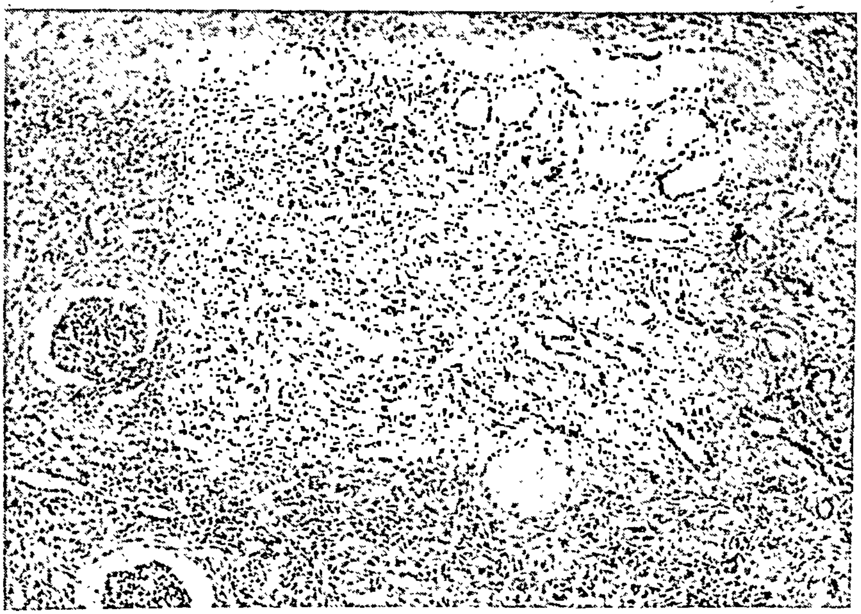

Fig. 4—Another part of the same kidney as in fig. 3, but distant from the tuberculous lesion; showing glomerular hypertrophy and sclerosis, interstitial scarring and inflammation, and tubular dilatation and hypertrophy, probably due to antecedent pyogenic pyelonephritis (hæmatoxylin and eosin × 104.)

On examination no cutaneous pigmentation was now visible. The blood-pressure was 180/130 mm. Hg, and a presystolic triple rhythm was audible in the heart. There was œdema of both ankles, and a small sacral pad, but the neck veins were not raised, and there was no pulmonary congestion. All the tendon-reflexes were very brisk, and Chvostek's sign was elicited. The urine, sp. gr. 1·010, contained protein 4 g. per litre and numerous granular casts. The serum-sodium level was 325 mg. per 100 ml. (142 m.eq. per litre); the serum-chloride 340 mg. per 100 ml. (96 m.eq. per litre); the alkali reserve 33·8 vols. per 100 ml. (15·7 m.eq. per litre); the blood-urea 150 mg. per 100 ml.; the serum-calcium 4·4 mg. per 100 ml. (2·2 m.eq. per litre); the serum-phosphate 4·26 mg. per 100 ml. (1·33 m.eq. per litre); the serum-potassium 17·1 mg. per 100 ml. (4·4 m.eq. per litre); the serum-creatinine 14·4 mg. per 100 ml.; the serum-alkaline-phosphatase 8·1 King-Armstrong units, and the serum-protein 6·15 g. per 100 ml. (14·9 m.eq. per litre).

Progress.—The patient rapidly developed generalised œdema, and on the

8th day (April 3) began to vomit. Over the next 2 weeks his persisted, and he developed gross muscular twitchings nd weakness. On the 32nd day (April 17) a pericardial riction rub was heard, and he died in uræmic coma on April 19, 34 days after admission.

Necropsy findings (Dr. J. B. Enticknap).—The adrenals were enlarged (20 g. each). Both kidneys were small, the left weighing 7·8 g. and the right 25 g. The left renal pelvis was larger than the kidney, and both ureters were dilated to a diameter of ·2 cm. (fig. 5). The right kidney was about four times as big as the left, but was still markedly reduced in size, and showed gross scarring of the surface. Perinephric adhesions were present on both sides, and section showed the cortex to be narrowed to about 2 mm. Histologically there were present changes typical of chronic pyelonephritis. The heart was enlarged (460 g.), and there was a recent fibrinous pericarditis. There was hæmorrhagic ulceration throughout the gut. The parathyroid glands and all other organs were normal.

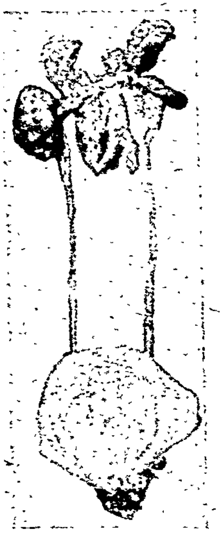

Fig. 5—Bilateral contraction of kidneys, left being much more affected than right and associated with dilatation and hypertrophy of pelvis and ureter (case 3).

DISCUSSION

Clinical Features

The six cases of salt-losing nephritis that have been previously reported comprise a clearly defined clinical group. The patients are usually young adults and, except for Thorn's patients, who experienced polyuria, have no history of renal disease or any symptom suggesting renal insufficiency. The illness presents with any or all of the symptoms of Addison's disease, including tiredness, weakness, anorexia, nausea and vomiting, cramps, collapse, and coma. All six of the reported cases and two of the three presented here (cases 1 and 3) were at one time diagnosed as adrenocortical failure, and this diagnosis was seriously considered in our other patient (case 2). In one patient carcinoma of the stomach was entertained as a possible diagnosis (Nussbaum et al. 1952).

Pigmentation of the skin, which has now been seen in three patients (Sawyer and Solez 1949, and the present cases 1 and 3), and the almost invariable absence of casts and cells from the urine make the diagnosis even more difficult. Some cases may be recognised by their failure to respond to deoxycortone acetate and adrenocortical extract or by the unusual degree of nitrogen retention and acidosis that exists. The diagnosis, if correct, can easily be confirmed by renal-function tests, which show gross impairment. Conversely, adrenocortical function, as shown by carbohydrate metabolism, 17-ketosteroid excretion, and response to adrenocorticotropic hormone (e.g., Thorn's test), will be found to be normal; whereas, tests of adrenal function that depend on intact renal tubules (e.g., the Kepler-Power test) are invalid in this condition.

Treatment by replacement of the lost sodium and chloride by doses of up to 20 g. of salt daily has enabled some patients to spend the rest of their lives in fair health. The longest recorded survival period has been 1½ years (Thorn et al. 1944). Correction of acidosis by sodium bicarbonate (15 g. per day) has been tried by Sawyer and Solez (1949), but Nussbaum et al. (1952), who used sodium acetate, observed that a restoration of the alkali reserve of their patient was associated with clinical deterioration and subsequent death.

The two common causes of death seem to be collapse in a state of salt depletion (de la Balze and Oñátivia 1947, and the present cases 1 and 2) and hypertensive heart-failure with uræmia (Thorn et al. 1944, and the present case 3), a fate which seems to await those in whom the salt loss has been successfully treated. In addition, these patients, like all nephritics, are ill equipped to overcome the other hazards of existence. One is reported to have died after a surgical operation (Sawyer and Solez 1949); another suddenly, possibly as the result of retention of potassium (Nussbaum et al. 1952); and a third from pulmonary tuberculosis (Borst 1950), a disease which two of our three patients had (cases 1 and 2). It is recognised indeed that in case 2 the picture of renal salt loss was complicated by the concomitant tuberculosis, which, for example, led to the appearance of pus cells and considerable amounts of protein in the urine. Further, it is arguable that the illness was in some degree due to active tuberculosis. These reservations are valid, but nevertheless we consider on clinical and biochemical grounds that sodium depletion was the most important feature of his illness.

Pathological Features

The biochemical findings in this type of nephritis are those of loss of salt and water together with nitrogen retention and acidosis. It is evident that these patients must all be in negative sodium, chloride, and water balance, although these crucial observations have never been recorded.

Kidneys.—Necropsy findings have been reported in five previous cases. Chronic glomerulonephritis was seen in three (Thorn et al. 1944, Sawyer and Solez 1949); polycystic disease, with apparent specific tubular damage, in one (Borst 1950); and pyelonephritis in another (Nussbaum et al. 1952). Two of the present cases showed chronic pyelonephritis (fig. 1), and one tuberculosis and chronic pyelonephritis (figs. 3 and 4). In case 1 (fig. 2) calcification of the tubules was seen, a finding previously reported by Thorn et al. (1944) and Sawyer and Solez (1949). The functional impairment is of the whole kidney, but the special features of this condition suggest that the tubules are specifically damaged. This is to some extent supported by the anatomical observations already cited, and further by the observations that the tubules do not respond to deoxycortone acetate, parathyroid, or pituitary extract (Thorn et al. 1944, Borst 1950), or to cortisone (Nussbaum et al. 1952), and that renal secretion of ammonia is decreased (Thorn et al. 1944).

Serum changes.—Thorn et al. (1944) graphically demonstrated that the abnormality of serum-electrolytes is due to failure not of production of adrenal cortical hormone but of tubular response. This principle of "target organ" failure has recently been recognised in other conditions—e.g., pseudohypoparathyroidism (Albright et al. 1942). The derangement of renal function underlying nitrogen retention is better understood (Fishberg 1939) than are those which cause acidosis and loss of salt and water. Platt (1951), however, has shown that in most cases of chronic renal failure sodium balance is still maintained, and that, because glomerular-filtration of sodium is diminished, this must imply a decrease in reabsorption of sodium by the tubules. In a few patients (Platt 1950) sodium loss was noted, and these may be regarded as potential salt-losing nephritics. Attention may also be drawn to the work of Pitts and Alexander (1945), who showed that the cells of the renal tubules can exchange hydrogen ions for sodium ions from the glomerular filtrate, and thereby eliminate acid and conserve base. Should this mechanism fail, acidosis together with excessive loss of salt and water would result, a condition similar to that seen in "salt-losing nephritis." Bull et al. (1950) have observed electrolyte loss in the recovery phase after prolonged anuria, when the tubules are specifically damaged, but this is a further acute episode in the course of a dramatic renal illness, and clinically distinct from "salt-losing nephritis." In this connection it may be noted that case 2 had two short periods of anuria (6 hours and 24 hours). His blood-pressure was not, however, very low during either episode, and we do not feel that they were causally related to his salt loss.

If the state of acidosis were of sufficient duration, sources of base other than sodium would have to be found. Albright and Reifenstein (1948), basing their calculations upon results obtained by Shohl (1939), conclude that 49% of the calcium in the skeleton is available as a source of base. This might eventually be drawn on and, should the drain be excessive, the picture of renal osteodystrophy result. This point has been fully discussed by Snapper (1949), but it is interesting to note that in case 3 the serum-calcium level was reduced to 4·4 mg. per 100 ml. (2·2 m.eq. per litre), and that the skull in case 1 resembled that seen in Paget's disease, being thickened and soft, a finding common in renal osteodystrophy. A further point of resemblance is the metastatic calcification noted by Sawyer and Solez (1949). Excessive excretion of calcium might explain the calcification which these workers found in the glomeruli and tubules. Tubular calcification was seen in case 1 (fig. 2).

Pathological pigmentation of the addisonian type has once previously been recorded in this condition (Sawyer and Solez 1949). In the present case 1 it was classical, involving the buccal mucosa, pressure points, and normally pigmented areas. In case 3 it was not characteristically addisonian, but the brown blotches on the face were very striking when the patient was first seen in 1951. This finding too is common in renal osteodystrophy (Maddox 1932). No explanation is offered for the occurrence of addisonian pigmentation in salt-losing nephritis, but it seems unlikely that adrenal medullary failure plays a part in its production.

SUMMARY

Three new cases of salt-losing nephritis, with necropsy findings, are reported.

The previously recorded cases are briefly reviewed.

The clinical features of the condition are summarised.

Two further cases showing pathological pigmentation of the skin are recorded.

The pathology of the condition is discussed.

Certain points of resemblance to renal osteodystrophy are noted.

We wish to thank Mr. W. D. Doherty and Dr. K. S. MacLean under whose care cases 2 and 3 were admitted; Dr. J. B. Enticknap for the histological reports and photomicrographs in all three cases and for the necropsy report in case 3; and Dr. J. C. Houston for helpful criticism and advice.

THE CONDITION OF THE KIDNEYS IN SALT-LOSING NEPHRITIS

J. B. Enticknap
M.D., D.C.P.

From the Department of Pathology, Guy's Hospital, London

Thorn et al. (1944) reported 2 cases of a clinical syndrome which closely resembled Addison's disease and in which pathological changes were found only in the kidneys, the adrenal glands being normal. Several similar cases have since been reported by other workers (table I). The condition has recently been reviewed by Joiner and Thorne (1952a), who present 3 further cases seen at Guy's Hospital. Specimens from these patients were much alike, a fact which prompted a review of the pathological features of all the 8 cases hitherto reported.

MATERIAL AND METHODS

The published reports of the first 5 cases have been extracted and summarised, wherever possible in the author's own words. In 4 of these 5 cases the descriptions are full and detailed, but none of the reports includes a photomicrograph. For case 6 the original necropsy report was available together with paraffin blocks of one kidney, one adrenal gland, and a piece of skull. The necropsies in cases 7 and 8 were personally observed, and the relevant material was examined histologically by conventional methods.

RESULTS

These are summarised in the accompanying tables, and the last 3 cases have been illustrated by Joiner and Thorne (1952a). All the kidneys were affected by generalised disease, but in case 7, who had had a unilateral nephrectomy, much of the remaining kidney was destroyed by tuberculous pyelonephritis. The description of this organ both in the text and in the table is mainly concerned with the parts of it apparently unaffected by this process, in which it was thought that changes were present that had probably antedated the tuberculosis. Even if they did not they so closely resembled those due to pyogenic infection that the main argument is unaffected. While it is impossible to dogmatise on the lesions present in the first 5 cases, the published reports show that they are very similar to those found in the last 3.

Macroscopically (table I) these diverse kidneys had several common features. Ten of the twelve kidneys in which it was possible to make an estimate were contracted, and the presence of multiple cysts in the remaining two makes it unlikely that the weights are a measure of the amount of functioning renal tissue. In 5 of these 6 cases the contraction was bilaterally asymmetrical. Capsular adherence was common, the normal pattern was usually destroyed, and in all the cases but one the thickness of the cortex was reduced to less than 3 mm. The surfaces of the kidneys were granular, and cysts were seen in several cases. Some abnormality was present in the pelvis in all the 7 cases in which it was described.

Microscopically (table II) there were again numerous features in common. Reticular or radial scarring is specifically mentioned in 5 cases, in 2 no relevant comment is made, and in the remaining case the kidney was grossly distorted by the presence of multiple cysts.

The *interstitial tissue* in all the cases showed various amounts of fibrosis and was infiltrated by cells denoting chronic inflammation.

The *glomeruli* were variably affected in the different kidneys, but in none were the changes of active glomerular nephritis seen, and all the descriptions suggest or emphasise the fact that the changes were not evenly distributed. Capsular thickening was present in all the cases, but in only 1 were adhesions to the tufts described.

The *tubules* showed changes in all the cases. Some dilatation was present in them all, and the descriptions of the other features of the first 5, although varying in detail, were compatible with the presence of the lesion that was seen in the last 3: focal hypertrophy producing an epithelium of variable depth in dilated subcapsular tubules that alternated with scarred areas in which the tubules were atrophied. The so-called colloid casts were present in 5 cases, and hyaline and granular material in another. Pus cells were present in the tubules in 4 cases, but 1 of these was the case with renal tuberculosis. Calcification of the tubular basement membrane was seen in 3 cases, and focal glomerular calcification in 2.

Other Findings.—In 2 of the cases there was hypertrophy of the parathyroid glands, but in only 1 of these and in 1 other in which they were normal was there any osteomalacia. There was also a tendency to hypertrophy of the adrenal glands, the weights in the 3 patients for whom they are recorded being above the normal mean, and hyperplasia being described in another case.

Diagnosis.—In 4 of the 7 cases in which a definite pathological diagnosis was made the condition was said to be pyelonephritis.

DISCUSSION

These findings suggest that chronic pyelonephritis is the condition commonly responsible for this syndrome; so it becomes important to define this term. As used here it is almost synonymous with the chronic interstitial nephritis of the older descriptions, a term which might well be applied to all the kidneys referred to. Its main feature is the presence of a chronic inflammatory exudate in the interstitial tissue causing renal contraction that is commonly greater on one side than the other. Microscopically a reticular type of fibrosis (Russell 1929) is seen, and the most typical lesion is a radial band extending from the pelvic region to a coarse depressed stellate scar on the surface. Parenchymal lesions are mainly confined to these bands of scar tissue, in which tubular atrophy and glomerular hyalinisation together with arteriolar sclerosis and hyalinisation are commonly found. In between these scars tubular hypertrophy and dilatation are present, and in many cases this proceeds to the stage of formation of small cysts in which the so-called colloid casts may be seen. Eventually numerous large cysts may develop, a condition much more commonly due to interstitial fibrosis than to the parenchymal inflammation of a predominantly glomerular nephritis (Weiss and Parker 1939). Numerous smaller points of differentiation have been described but are not sufficiently exclusive to be of real diagnostic value.

I have discussed elsewhere (Enticknap and Joiner 1952) whether the term "chronic pyelonephritis" is the best name for the condition present in kidneys showing these appearances, and have provisionally concluded that it is. In such cases that present, as these subjects did, with some form of renal failure, the disease has probably developed from repeated minor attacks of hæmatogenous renal infection following asymptomatic transient bacteræmias. It is becoming increasingly recognised (see Enticknap and Joiner 1952 for references) that this condition is perhaps the commonest single form of Bright's disease; hence it is not surprising that several of the cases in the present series were so diagnosed and that they were the ones more recently published. The first 4 cases may therefore be re-examined to see whether they too are not examples of a similar condition. Cases 1 and 4 and cases 2 and 3 will be discussed together because they present similar appearances.

Cases 2 and 3 both have much contracted kidneys from which nearly all pathognomonic changes have disappeared, and it is perhaps unwise to attempt to diagnose them too precisely solely from the condition of the kidneys. Clinically case 2 had only a trace of protein in the urine, whereas case 3 had none, and in neither case were casts found, findings quite unlike those of the terminal stages of chronic glomerular nephritis. A further point is that case 2 had hypertrophy of one parathyroid gland and softening of the ribs. Gilmour (1947) showed that secondary hyperparathyroidism in acquired renal

TABLE I—MACROSCOPIC APPEARANCES OF KIDNEYS

Case no.	Reference	Original author's diagnosis	Kidney weights (g.)		Capsule	Surface	Normal pattern	Pelvis
			R	L				
1	*Thorn et al.* (*1944*): Case 1	None given	140	140	Adherent	Finely granular and showing numerous cysts	Destroyed by cysts, cortex reduced to a few mm.	A few submucosal hæmorrhages
2	Case 2	Diffuse glomerulonephritis in the final state	60	42	Adherent and thickened	Finely granular with a few cysts	Destroyed, a few cysts present, cortex 1·0–2·5 mm. thick	A few hæmorrhages and some increase in fat
3	*Sawyer and Solez* (*1949*)	Severe chronic glomerulonephritis	70	70	Adherent	Finely granular	Poorly demarcated, cortex 3 mm. thick	Submucosal hæmorrhages
4	*Borst* (*1950*)	Bilateral cystic disease	Combined weight 770		..	..	Innumerable cysts, from pinhead size to 3 mm. in diameter	..
5	*Nussbaum et al.* (*1952*)	Acute superimposed on chronic pyelonephritis	80	110	Adherent	A few cysts	Cortex of normal thickness	Purulent exudate
6	*Joiner and Thorne* (*1952a*): Case 1	Chronic pyelonephritis	18	31	Stripped fairly readily	Granular with depressed scars	Not present	Small papilloma
7	Case 2	Tuberculous pyelonephritis	..	232	..	Mottled with yellow areas	Distorted by tuberculosis	Slightly dilated, ureter thickened
8	Case 3	Chronic pyelonephritis	25	8	Adherent to kidney and perinephric tissue	Coarsely granular with depressed scars and a few cysts	Destroyed, a few small cysts present, cortex 1–2 mm. thick	Dilated to twice the normal size on side of smaller kidney; a few hæmorrhages

disease was found almost exclusively in chronic pyelonephritis, a finding which agrees with experience in this hospital (Joiner and Thorne 1952b). Finally it may be pointed out that the label "glomerulonephritis" attached to these cases by the original American workers does not necessarily preclude their being examples of chronic pyelonephritis as defined, for it may merely reflect the absence of agreement on the significance of the terms used in renal pathology. It is therefore concluded that these 2 cases are examples of contracted kidneys in the sense that the term has been used elsewhere (Enticknap and Joiner 1952); and, although the question of their origin must be left undecided, it was found in the investigation referred to that such kidneys occurred most commonly in patients thought clinically to have chronic pyelonephritis.

Both cases 1 and 4 had kidneys containing multiple cysts and accordingly of normal or increased weight. In case 1, not diagnosed by Thorn et al. (1944), there can be little doubt from the description that the condition was inflammatory and almost certainly due to chronic pyelonephritis. Much parathyroid hyperplasia was again present. The weight of the kidneys in case 4 makes this diagnosis much less likely, but the description given is fragmentary. Probably the correct diagnosis is congenital polycystic disease, but the fact that this patient was not hypertensive makes this uncertain. In any event such kidneys commonly show evidence of superadded infection, fibrous replacement of renal parenchyma following repeated attacks being the probable morphological basis of ultimate renal failure, and much proliferation of interstitial connective tissue is emphasised in the description. Case 1 is then almost certainly one of chronic pyelonephritis, and case 4, although probably having some other renal abnormality as well, shows changes that strongly suggest the presence of the same condition.

TABLE III—OTHER FINDINGS

Case no.	Para-thyroid glands	Bones	Adrenal glands	Other necropsy findings	Urine
1	5·7 g.	Normal	16·5 g. and 24 g.	..	No proteinuria and no casts
2	1 of the 3 found was larger than normal	Ribs soft	7·5 g. and 8·8 g.	..	Trace of protein and no casts
3	Normal	Normal	Hyperplasia	..	No protein and no casts
4	..	..	Normal	Hilar node, pulmonary and miliary tuberculosis	..
5	..	..	Normal	..	..
6	..	Skull soft but histologically normal	Normal	..	..
7	Normal	Normal	Normal	Previous unilateral nephrectomy for tuberculosis	..
8	Parenchyma weight 105 mg.	Normal	Large, about 20 g. each	..	..

Extensive tubular changes, giving rise in most cases to cyst formation, are a uniform feature of the histology of these kidneys. This is of interest in view of the conclusion of Joiner and Thorne (1952b) that the tubules are the site of the biochemical abnormality.

In summary it may therefore be said that 4 of these

TABLE II—MICROSCOPIC APPEARANCES OF KIDNEYS

Case no.	General appearance	Interstitial tissue	Glomeruli	Glomerular capsules	Tubules	Casts and tubular contents	Calcification of tubules
1	Extensive scarring widely separating cystic tubules and atrophied glomeruli	Hyaline fibrosis with plasma cells, mononuclears, and lymphocytes	Mostly hyalinised; preservation of single tufts in a few only	Pericapsular fibrosis	Dilated; flattened epithelium	"Colloid" casts	Present
2	..	Numerous lymphocytes	Mostly hyalinised; remainder hypertrophied; a few capillary thrombi	Adenomatous proliferation of epithelium; a few hyaline crescents	Dilated and hyalinised proximal tubules	Hyaline, granular, pus-cell, and "colloid" casts	..
3	..	Increased connective tissue; round cells	Reduced in number; mostly hyalinised, some lobulation and calcification	Thickened and adherent to tufts	Patchy distribution of atrophy and hypertrophy	None	Prese
4	Multiple cysts	Much proliferation of connective tissue	Those present are intact	..	Severe degenerative changes, especially inconvoluted tubules; 2nd c.t. dilated	2nd c.t. contain hyaline and granular material	..
5	Patchy scarring	Increased fibrous tissue, with lymphocytes and plasma cells	Some degeneration	Thickened	Hypertrophy and dilatation	"Colloid" casts and pus	..
6	Reticular fibrosis with changes most marked in the radial scars	Gross fibrosis and some pus cells	Some hypertrophied and others with focal capillary hyalinisation and calcification	Some pericapsular fibrosis	Atrophy dilatation and hypertrophy; a few cysts 1–4 mm. in diameter	"Colloid" casts and some pus cells	Presen
7	Radial areas of tuberculosis; radial scarring	Fibrosis and round-cell infiltration	Hyalinisation in radial scars only	Some fibrosis	Dilated and hypertrophied between scars in subcapsular region; destroyed elsewhere	Pus cells	..
8	Reticular scarring and gross distortion	Increased fibrous tissue and lymphocytes	Mostly hyalinised	Thickened	Atrophy, dilatation, and hypertrophy	"Colloid" casts	..
			A few grossly contracted glomeruli within dilated capsules showing plicated endothelium				

cases had chronic pyelonephritis in association with the salt-losing syndrome. In 2 further cases there was present in addition another serious renal condition, tuberculous pyelonephritis in one, and a form of cystic disease in another. In the remaining 2 patients inflammatory fibrosis had caused such gross distortion of the kidneys that it was impossible to be certain of the initial condition, which may well, however, have been pyelonephritis. In view of these findings it may be questioned whether salt-losing *nephritis* is the best possible name for this very important syndrome, and I suggest that, until the biochemical abnormality responsible is elucidated, it is better to use a circumlocution such as "urinary salt loss due to renal disease" or, perhaps much more neatly, "Thorn's syndrome."

SUMMARY

The renal findings in the 8 published cases of the salt-losing nephritis syndrome of Thorn et al. (1944) are described.

Chronic pyelonephritis was certainly present in 4 of them, probably present in 6 of them, and may well have been present in all 8 cases.

Since this condition is the only common pathological feature of these cases, the syndrome is probably an unusual response to it and the term "salt-losing *nephritis*" is not an accurate description.

UNIVERSITY OF BIRMINGHAM

ALTHOUGH for the past thirty years neuromuscular dysplasia or incoördination has been accepted as the cause of congenital megacolon (Hirschsprung's disease), and has supplanted the theory of valves or kinking of the colon at the rectosigmoid junction as the result of fæcal loading, a better understanding of the pathogenesis of the condition has been given by the work of Bodian et al. (1949) and Swenson et al. (1949).

Sir Arthur Keith (1915) was aware that much could be learnt of the pathology of the colon by a study of the "Auerbach tissue," as he called the functioning complex of ganglia and nerves lying within the muscle of the gut. He investigated its anatomy and pathology when Arbuthnot Lane was doing colectomy for intestinal stasis, and the discovery of some abnormality in the neuromuscular complex was anticipated as corroborative evidence in support of such treatment. Keith did not claim that the genesis of stasis had been solved:

> "Although my investigations have not succeeded in finding a pathological basis for impaired mobility of the colon, they may be of service in another way, by drawing attention to our considerable ignorance concerning both the anatomy and physiology of the great bowel."

Surgical textbooks of the day—e.g., Miles (1923)—always pointed out that there were two types of megacolon: one in which dilatation and hypertrophy extended from the anus upwards, and another in which various lengths of the rectum appeared normal in every respect. It is in this second type that Bodian et al. (1949) have shown an abnormality of "Auerbach tissue" in the seemingly normal portion of the rectum—namely, absence of ganglion cells, with some increase in size of the nerve-fibres. Swenson et al. (1949) have also demonstrated this abnormality and confirmed it by the manometric recordings of peristalsis. However, they do not suggest that there is absence of ganglion cells in all cases of congenital megacolon. Until this work, attention had always been focused on the dilated and hypertrophied portion of colon.

In view of these recent observations it has been suggested that the term congenital megacolon should be restricted to the second of the above-mentioned types, which usually manifests itself shortly after birth, the other types of megacolon with achalasia of the anal sphincter being excluded (Stephens 1951). Although this conception is based upon the time of onset of the disease in the life of the patient, together with the histological findings, it is really necessary to have proof of absence of some structure or of some function of the anal canal before such a distinction can be made permanently. Congenital weakness or imbalance may not show itself in the first few years.

The life history of these unfortunate victims who are deprived of the means of normal rectal and colonic evacuation is chequered with constipation and crises of such a degree of fæcal retention and impaction that, besides the effect of toxin absorption, peritonitis and death may result from perforation of stercoral ulceration. The least discomfort that the patient can have to endure is a rectal washout every week or so, and periodic manual evacuation of the rectum superimposed upon the obstinate constipation. If the lesion is more than a few inches from the anal canal, such conservative measures as rectal dilators and rectal washouts have little or no chance of permanent success compared with those cases of achalasia of the anal sphincter which Hurst (1924) declared could be treated in this way. Spinal anæsthesia (Telford and Simmins 1939) may be effective if given early enough in the life of the child, but a permanent result cannot be expected where "Auerbach tissue" is absent.

What is the quality of the life of one who suffers from this absence of "Auerbach tissue" and what is its duration? The quality is poor, being probably due to the absorption of toxins from the colon, for the general health is not good and the body is thinly covered and undernourished. The duration may be as short as a few weeks; but, even if early crises are survived, death may come from perforation or from intercurrent infection in adolescence. Adult life is rarely attained. Published reports give little or no information about the effect on physical and mental development or on endocrine balance that the condition may have if the patient survives; and no worker has reported such a remarkable delay in development, followed by an even more remarkable transformation after colectomy, as in the case described here.

CASE-RECORD

The patient was born in 1931. At the age of 11 days he was admitted to hospital with vomiting and signs of intestinal obstruction, and this early crisis was overcome with conservative measures. For the next 3 years the boy was in and out of various hospitals with attacks of obstruction. At the age of 3 years he was brought to the Children's Hospital, Birmingham, and there diagnosed as a case of Hirschsprung's disease. Admission was advised, but while he was on the waiting-list he had a further attack of obstruction. This time the distension and colonic impaction of fæces were so severe that a hard core of fæces was protruding through the anus. One of us (F. A. R. S.) did a cæcostomy and manual evacuation of the rectum as an emergency device to afford relief. Later on in his 3rd year the boy underwent presacral sympathectomy and section of the lumbar colonic nerves; but no permanent relief was obtained, and his abdomen remained grossly distended. Yet there was some improvement, and because of this, and because of the war, he was lost sight of until he was aged 18, when he was admitted to Queen Elizabeth Hospital, Birmingham, for further investigation and treatment because he never had a spontaneous bowel action, fæcal impaction being prevented by enemata every other day. He had found that he could sometimes pass flatus if he lay steeply inclined with the pelvis high, so that the sigmoid could straighten out by gravity. He sought advice because his abdominal distension caused increasing breathlessness on exertion.

On examination he was very small, like a child aged 10 years rather than 18; his voice had not broken, his genitalia were undeveloped, and he had no pubic or axillary hair. His abdomen was enormously distended (fig. 1), and peristaltic waves were visible, often preceded by pain sufficient to make him cry out.

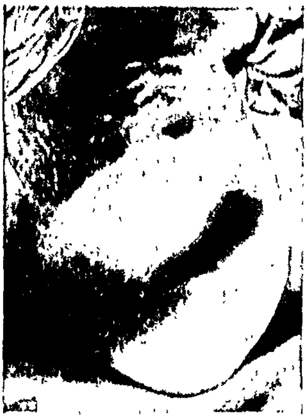

Fig. 1—Enormous distension of abdomen, tiny chest, and flaring of ribs.

Investigations.—The blood-pressure was 100/60 mm. Hg. Blood-count: hæmoglobin 30%, red cells 3,500,000 per c.mm.—a severe microcytic hypochromic anæmia.

Radiography of the chest was normal. The report on the abdomen was: "One can only call the fæcal accumulation fabulous." The report on the epiphyses was: "The bones are slender with wide marrow cavities. The union of the epiphyses to the shafts is a little delayed. That for the radial head should have fused at puberty; that at the distal end of the humerus should just be fusing."

Progress.—Even while enemata were being given to remove the accumulation of fæces the patient developed obstruction with vomiting and increase in the distension, but the crisis was overcome by further washings, and during the following fortnight enormous stools were obtained. The abdomen became much softer, but the large hypertrophied colon could easily be felt. It was decided to do a laparotomy to see if anything, possibly a colectomy, could be done to help the patient.

Operation (F. A. R. S.).—On July 18, 1949, the abdomen was opened through a left paramedian incision. Gross hypertrophy and dilatation of the ascending, transverse, descending, and sigmoid colon were found. The mesocolon and mesosigmoid were enormously thickened. The cæcum was normal. At the rectosigmoid junction the bowel suddenly narrowed, and the lumen appeared constricted for half an inch, at which point there seemed to be an increase in the circular muscle fibres; distal to this point the bowel was narrow (fig. 2). It was decided that a colectomy was contra-indicated by the patient's poor condition and by his patulous anal sphincter, which would probably leave him incontinent after a colectomy with anastomosis of the ileum to the rectal stump. It was suggested that a plastic procedure like that used in Heller's operation for cardiospasm or in the Fredet-Rammstedt operation for pyloric stenosis in infancy could be tried. This plastic procedure at the site of constriction was undertaken, and longitudinal and circular muscle-fibres were divided vertically for three inches, and the incision was deepened until the mucosa began to pout through the incision. The rectum was not opened, but the bared area with pouting mucosa was covered by overlapping the appendices epiploicæ from each side; a pelvic drainage tube was inserted as a safety measure in case of leakage. The abdomen was closed.

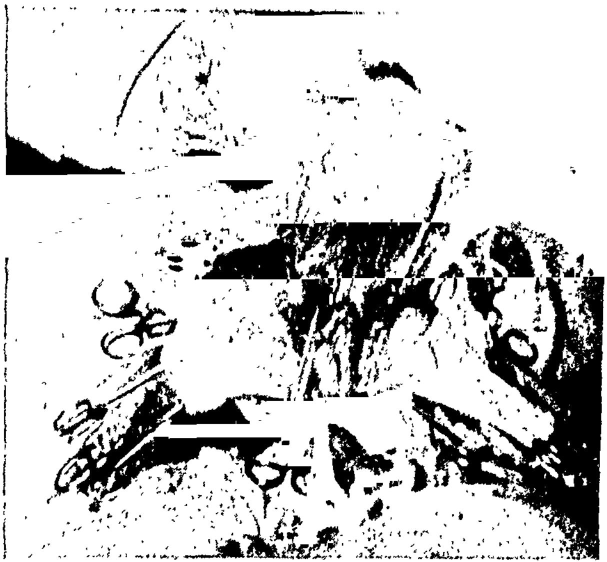

Fig. 2—Thickened dilated sigmoid colon joining apparently normal rectum found at plastic operation.

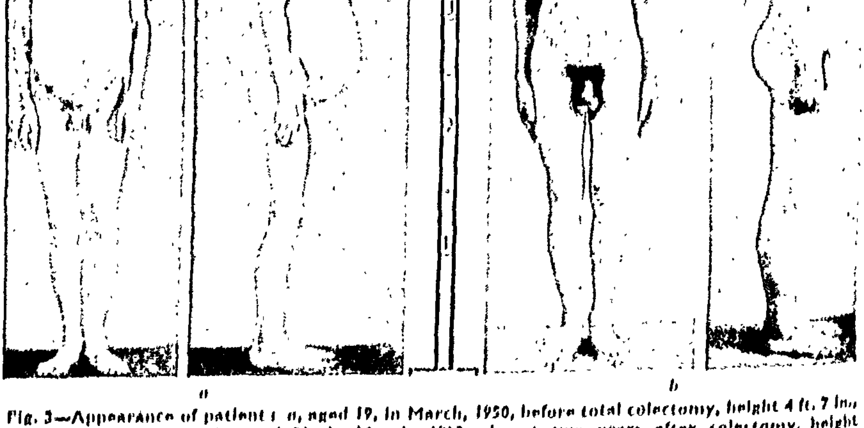
Postoperatively the patient could pass flatus through the tube, and 4 days later he had a spontaneous bowel action. From then on he had several actions of good amount each day, and his general condition was much improved. He was delighted, because this was the first time in his life that he had ever had a spontaneous action.

On discharge his hæmoglobin had risen from 30 to 60%, his abdomen was considerably less distended, and he was learning abdominal exercises so that the muscles could regain their tone after being continually overstretched.

Relapse.—After 3 months of spontaneous bowel actions constipation recurred, and in 6 months the patient was admitted to another hospital as an emergency case with



a *b*

Fig. 3—Appearance of patient: *a*, aged 19, in March, 1950, before total colectomy, height 4 ft. 7 in., weight 5 st. 11 lb.; *b*, aged 21, in March, 1952, almost two years after colectomy, height 5 ft. 4 in., weight 8 st. 7 lb. Note recovery of stretched abdominal muscles in spite of operation scars.

obstruction of the large bowel. This obstruction was temporarily relieved by enemata, and after this he was admitted once more under one of us (F. A. R. S.). This time it was decided that total colectomy with anastomosis of the lower ileum well down on to the apparently normal rectum offered the only chance of success. The patient was now aged 19 and still looked as poorly nourished and infantile as before, and the distension of his abdomen was considerable (fig. 3*a*). His hæmoglobin was 46% and red cells 3,000,100 per c.mm. Repeated blood-transfusions were given before operation, raising the hæmoglobin to 86% and the number of red cells to 4,700,100 per c.mm. The serum-chloride and serum-protein levels were normal.

Total colectomy (F. A. R. S.).—On April 4, 1950, laparotomy was done through a midline incision, and the huge colon was found with many adhesions over the cæcum. The bowel at the rectosigmoid junction, where the previous plastic operation had been done, was found to be dilated, and below this the rectum appeared normal in size and on palpation. The site of the plastic operation was almost obliterated by scar tissue. Total colectomy was done (fig. 4). The distal ileum was anastomosed end-to-side with the rectum after the upper cut end of the latter had been closed by invagination.

Postoperatively the patient's general condition was good, but in the first 2 days he had severe abdominal colic, and it was noticed more than ever how child-like the patient was in his response to the pain and considerable discomfort. On the 3rd day he passed fæces and flatus; on the 4th and 5th day he had diarrhœa, having his bowels open five and seven times a day; on the 6th day his bowels were opened twice; and subsequently, although the motions were loose, he had no more than two or three actions daily until he was discharged on April 22, 1950.

Pathological report on the apparently normal area below the dilated sigmoid: "Ganglion and nerve-fibres present in the position of Auerbach's and Meisner's plexuses. The muscularis of the colon below the stricture shows infiltration with lymphocytes and plasma cells."

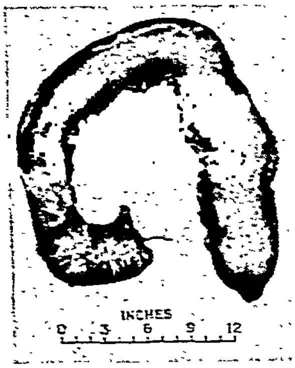


Fig. 4—Colon removed at second operation. Note foot rule and size of appendix, which escaped dilatation and hypertrophy.

Follow-up.—Two years have gone by since the colectomy: and in that time, besides maintaining spontaneous rectal evacuation from once to three times a day with no looseness or diarrhœa, the patient has been physically and mentally transformed. He is now aged 21, with a healthy agile mind and body (fig. 3*b*), looking forward to hard work and a good future. He is an engineering apprentice and in his spare time enjoys cycling and a great deal of ice skating. In April, 1952, he was 5 ft. 4 in. in height (4 ft. 7 in. before colectomy) and 8 st. 7 lb. in weight (5 st. 11 lb. before). The genitalia have developed, and all secondary sexual characteristics are present. His hæmoglobin is 92%, and radiography of the long bones shows (Dr. J. F. Brailsford) "evidence of some delay in ossification. The appearances suggest that the skeleton temporarily retarded has established its potential growth. The main epiphyses have now fused. There is no indication of giantism."

DISCUSSION

Diagnosis

The history of obstinate constipation from birth, with failure of spontaneous bowel action until the plastic operation at the age of 18, the crises of fæcal impaction, the failure of more conservative operations, together with the typical appearance shown by a fractional barium enema and the findings at operation (fig. 2), mark the patient as having congenital megacolon with dysplasia of the apparently "normal" segment of the rectum.

Rationale of Operation

For the extreme distension of fæcal impaction in a small child cæcostomy is a life-saving operation, overcoming obstruction and preventing perforation from stercoral ulceration; and the consequent improvement in the patient's condition makes it possible to empty the large bowel with less risk. There is no doubt of the good effect obtained in the present case.

Some operations become popular as the result of experimental work on a particular subject, and this was true in the early 'thirties of presacral neurectomy and section of the lumbar colonic nerve following the contributions of Learmonth and Markowitz (1930) and Rankin and Learmonth (1930) to the understanding of the autonomic system in the pelvis. Sympathectomy had just made its début, and reports of its application and results were beginning to come in (Stammers 1932). In the present case, however, there was no striking improvement. The plastic operation of 1949, done on the same lines as that for achalasia of the cardia or for congenital hypertrophic pyloric stenosis, was attended with some, though only temporary, success, for it was after this that the patient had the first spontaneous bowel action of his life. The cause of the failure may have been, just as it can be with rectosigmoidectomy, that the operation was not carried past the affected area of rectum. Had this been done, success might have lasted longer, though it must be observed that in the temporary period of 6 months of success there was no improvement in growth and development.

Total colectomy and not rectosigmoidectomy was done because the colon had been dilated and hypertrophied for 19 years and was involved right up to the cæcum; toxic absorption from the colon was causing delay in growth and development; and total colectomy in one stage for ulcerative colitis is not considered dangerous provided that the water and electrolytic balance of the patient is maintained. Colectomy for intestinal stasis on the grounds that it causes absorption of toxins was advocated and practised by Lane (1915) and Ward (1915).

The remarkable result that attended total colectomy in the present case supports the theory of toxic absorption (Mutch 1915), for some factor must have entered the body from the colon to retard growth and development to such an extent. One may wonder whether the same result would have been obtained by rectosigmoidectomy, by which operation the affected area of apparently normal rectum would have been excised but the proximal colon would have been retained. This may well be doubted, since no such change followed the plastic operation, although spontaneous bowel actions occurred.

Little is known of the toxins that can be absorbed from the bowel or be responsible for such a condition. Although such absorption is held to be the cause of a sallow-skinned and poorly developed body with equivalent mental features, as is often seen in those who have prolonged obstinate constipation, this patient's mind and agility were of a high standard considering the stress imposed by the protuberant abdomen. Some other "toxin" must have been absorbed which had a direct effect on the pituitary gland.

In the last few years interest has been focused on necessary growth-promoting substances, such as vitamin B_{12}, and their association with bacterial activity and antibiotics. Perhaps in megacolon the absorption of these substances is prevented by the effects of stagnation in the dilated large bowel, effects which may even cause severe retardation of endocrine function. The more recent discovery of the rôle of pantothenic acid as an enzyme in the formation of acetylcholine may provide further impetus for research in Hirschsprung's disease. Although Swenson et al. (1949) have shown that the ganglion cells were absent in some of their cases, they state that this is not always so, this point being borne out in the case reported here. Perhaps an upset of the normal bacteriology of the colon, with incomplete synthesis of pantothenic acid and the failure to absorb growth-promoting substances, may be responsible for much of the pathology of Hirschsprung's disease. Though this is conjecture it is an additional pointer to the fact that the pathology of Hirschsprung's disease is not yet completely known.

TREATMENT OF THE ADRENOGENITAL SYNDROME WITH CORTISONE

DOUGLAS HUBBLE
M.D. Lond., M.R.C.P.

PHYSICIAN, DERBYSHIRE ROYAL INFIRMARY, DERBY CITY HOSPITAL, AND DERBYSHIRE HOSPITAL FOR SICK CHILDREN

THE manifestations of the adrenogenital syndrome in girls and women at or after puberty respectively are hirsuties, acne, enlargement of the clitoris, and amenorrhœa or irregular scanty menstruation. Although some of these patients may have a daily excretion of 17-ketosteroids within average limits (5–15 mg.), if the output of 17-ketosteroids is followed over a long period it can be shown in many instances to exceed 20 mg. daily. This increased excretion is intermittent and varies in amount; it has been reported by Koets (1949) to be greatest in the phase of ovulation, and by Merivale (1951) to be maximal in the luteal phase. The recognition that cortisone depressed adrenocortical function soon led to its use in conditions of adrenocortical excess. Wilkins et al. (1951, 1952) have described its use in eleven children for 5–17 months, and Bartter et al. (1951) have described the results of treatment in three patients. Bishop et al. (1952) and Simpson (1952) have reported its use for a short time in two patients with adrenocortical hyperplasia.

In the case reported here a girl, aged 19, with virilism, was studied for ten months, during the last five of which she was treated continuously with cortisone.

CASE-RECORD

The patient, who was referred to me from the dermatological department of the Derbyshire Royal Infirmary by Dr. P. D. C. Kinmont for investigation of hirsuties, complained of an excessive growth of hair on her face since the age of 15, more marked on the cheeks than on the lip and chin (see figure). She shaved three or four times a year. Her menses started at the age of 13 and were irregular during the first two years, with periods of amenorrhœa lasting three or four months. From the age of 15 to that of 17 the intervals between periods were about a month, but during the last year usually 31–33 days.

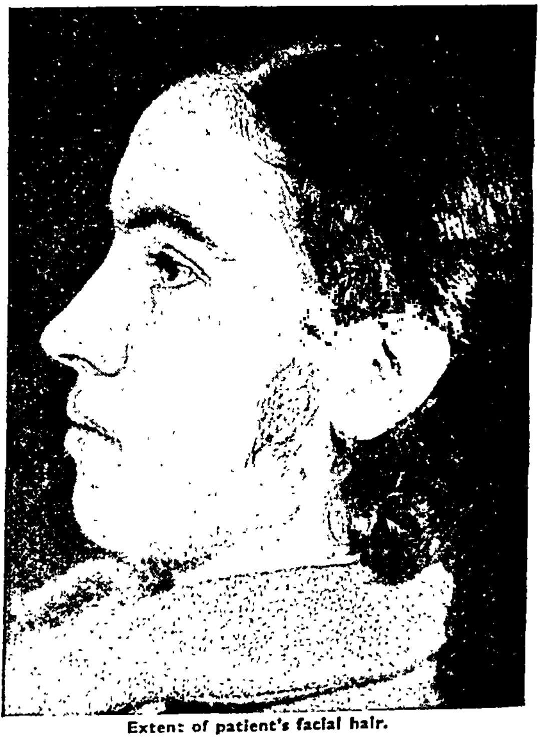
On examination the patient had a few hairs round the areolæ of the nipples and a male distribution of hair on the abdomen. The growth of hair on the back and on the legs was excessive. There was a moderate amount of acne on the face and back. The labia minora were reported by a gynæcologist (Mr. N. L. Edwards) to be hypertrophied, and the clitoris to be enlarged.

Investigations.—A tumour of the adrenal cortex was excluded, and the usual endocrine functions were investigated and found to be within average limits except in two aspects. The urinary excretion of 17-ketosteroids was intermittently greater than usual. In 25 estimations done in five months the average daily excretion was 15·2 mg. per twenty-four hours, the lowest figure being 7·0 mg. and the highest 33 mg. per twenty-four hours. It could not be determined that the rise or fall of 17-ketosteroids was related to definite intermenstrual phases, nor were the highest levels associated with the increase of pregnanediol in the luteal phase. The other abnormal finding was that on 6 out of 23 occasions the serum-potassium level was lower than normal; the lowest of these six readings was 12·2 mg. per 100 ml. (3·1 m.eq. per litre), and the average 14·5 mg. per 100 ml. (3·7 m.eq. per litre). On three of these occasions the serum-sodium level was above normal: 334, 340, and 344 mg. per 100 ml. (145, 147, and 149 m.eq. per litre). The plasma-chloride level, the alkali reserve, and the urinary output of sodium, potassium, and the chlorides were invariably within accepted average limits. The eosinophil-count was always between 200 and 500 per c.mm.

Treatment.—The patient was first given a week's treatment with 100 mg. of A.C.T.H. daily. This produced an eosinophil-count averaging 60 per c.mm. (ten counts), and an excretion of 17-ketosteroids averaging 24·0 mg. per twenty-four hours (six estimations). The day-time output of urine in the five days preceding A.C.T.H. therapy was 182 oz. (daily average 36·4 oz.) and the nocturnal output 93 oz. (nightly average 18·6 oz.). In the first four days of A.C.T.H. therapy the day-time output was 84 oz. (daily average 21 oz.) and the nocturnal output 144 oz. (nightly average 36 oz.). The daily average serum-potassium level in the first four days of A.C.T.H. therapy was 13·9 mg. per 100 ml. (3·6 m.eq. per litre). In the last two days of the week of A.C.T.H. therapy the serum-potassium level was normal and the ratio of diurnal to nocturnal urine was corrected. At the end of five weeks, and before cortisone therapy was started, the patient's cheeks were shaved and the hair removed was weighed. This was repeated at the end of four further five-week periods, during which the dose and method of administration of cortisone varied (see table).

RESULTS OF TREATMENT

These findings confirm the therapeutic results obtained by Wilkins et al. in adrenocortical hyperplasia in children. Cortisone will suppress the excessive androgenic activity of the adrenal cortex, and Wilkins et al. suggest that, to sustain an optimal therapeutic effect, the excretion of 17-ketosteroids should be kept less than 8 mg. per twenty-four hours. In the present patient with varying dosage this level was maintained for periods of no longer than two weeks, and a detailed examination of the records suggests that this level might be permanently



Extent of patient's facial hair.

RESULTS OF CORTISONE THERAPY

—	First 5 weeks	Second 5 weeks	Third 5 weeks	Fourth 5 weeks	Fifth 5 weeks
Average daily dosage of cortisone (mg.)	Nil	50 (1)	25 (2a & b)	40 (3a & b)	40 (4a, b & c)
Weight of hair removed (mg.)	99	50	70·8	68	58
Average daily excretion of 17-ketosteroids (mg.)	20	10·3	11·5	10·5	10·4

Method of administration :

1, 25 mg. by injection twice daily.
2(a) 2 weeks, 50 mg. orally (? = 25 mg. by injection).
(b) 3 weeks, 25 mg. by injection daily.
3(a) 1 week, 25 mg. by injection twice daily.
(b) 4 weeks, 50 mg. by injection on alternate days.
4(a) 2 weeks, 50 mg. by injection on alternate days.
(b) 2 weeks, 25 mg. twice daily.
(c) 1 week, 100 mg. on alternate days.

sustained with a daily injection of 50 mg. or an injection of 100 mg. on alternate days. The same dose by mouth was ineffective, and Wilkins et al. advise that, for an equal suppressive action, the oral route requires two or three times the amount given by injection.

It will be seen from the table that there is a rough correlation between the amount of hair growth, the dose of cortisone, and the amount of 17-ketosteroids excreted. It is shown that the rate of excessive hair growth can be about halved, but that it can be completely suppressed by cortisone therapy is as yet uncertain.

MODE OF ACTION

It is assumed that cortisone suppresses adrenocortical activity by opposing the action of A.C.T.H. Bartter et al. suggest that the androgenic excess may be due to a relative insufficiency of 11,17-oxysteroid production (which is the major opponent and regulator of A.C.T.H. secretion) with a consequent excessive secretion of A.C.T.H.

The present patient showed no evidence of 11,17-oxysteroid insufficiency (including her response to a water load, to intravenous insulin, and to stress). Moreover, though A.C.T.H. 100 mg. daily produced an effect on 17-ketosteroid output and serum-potassium levels of the same order as had appeared intermittently in the preliminary control periods, it produced in addition a profound and sustained eosinopenic response. Clearly 11,17-oxysteroid production was not deficient in this patient either under ordinary conditions or in response to A.C.T.H.

DISTURBANCE OF ELECTROLYTES

It has long been recognised that adrenocortical hyperplasia in infants may be accompanied by excessive loss of sodium and that, though this is corrected as the child grows older, it tends to recur during infections. In Cushing's syndrome a low serum-potassium level is sometimes seen; and this may be sufficiently severe to produce the hypochloræmic alkalosis which is now recognised to follow a potassium deficit. It is assumed that this hypokalæmia is due to the excessive production of a steroid with a deoxycortone-like action. In this patient the low serum-potassium levels presumably resulted from the same cause.

Occasionally this hypokalæmia was accompanied by a serum-sodium level above normal; but, although examined on scores of occasions, no reduction of plasma-chloride level and no increase of CO_2-combining power beyond average limits were recorded. The hypokalæmia was not accompanied by fatigue, muscle weakness, or electrocardiographic change. This lack of correlation is now widely recognised. Since this observation of hypokalæmia in the adrenogenital syndrome has apparently not been made before, great care was taken to ensure that these results were accurate. They were checked against estimations made on other patients on the same day, they were frequently estimated by different methods, and they were usually duplicated in two laboratories.

In another patient with adrenocortical hyperplasia now being investigated a similar hypokalæmia has been observed:

A school-mistress, aged 24, complained that a considerable growth of hair had been present on her face since adolescence. She had a male distribution of hair on her abdomen. Her menarche was at the age of 18, and her menses are scanty, short, and irregular. Her breasts are normally developed, and her clitoris is moderately enlarged. Her average daily excretion, determined each day for 23 days, was 21·3 mg., the lowest daily value being 11 mg. and the highest 30 mg. The average daily serum-potassium level in a month was 14·3 mg. per 100 ml. (3·7 m.eq. per litre), and the average of seven daily serum-potassium levels obtained in another laboratory in the same period was 14·4 mg. per 100 ml. (3·7 m.eq. per litre).

POSSIBILITIES OF THERAPY

Though the treatment of adrenocortical hyperplasia in childhood, whether in female pseudohermaphroditism or in macrogenitosomia præcox in boys, is undeniably first-class therapy, it is uncertain whether adrenocortical hyperplasia occurring at puberty and after justifies continued treatment with cortisone. The suppression of the signs of virilism—hirsuties, menstrual disturbance, acne, and so on—may seem to be an inadequate reward for the frequent injections of a potentially hazardous substance. On the other hand, few conditions cause more distress to girls in adolescence and in young womanhood than does virilism, and, when cortisone is more freely available, such therapy, carefully controlled, may justifiably be practised. This condition is by no means rare and, since its effective treatment will require about 20 g. of cortisone a year, such therapy is not immediately practicable.

SUMMARY

The treatment of a patient with the adrenogenital syndrome (virilism) with cortisone for five months is described.

The amount of cortisone required for the suppression of excessive androgenic activity was about 50 mg. daily. This dosage slowed the rate of facial hair-growth by about half.

The finding of intermittent hypokalæmia in this patient and in another with the adrenogenital syndrome is reported. This parallels the potassium deficit which sometimes occurs in the adrenocortical (Cushing's) syndrome.

This paper is the report of a great deal of investigation, much of it here unrecorded, conducted by several technicians. The chemical investigations were made in the laboratory of the Derbyshire Royal Infirmary (Dr. G. R. Osborn) by Mr. J. A. Allen, Miss A. Matthews, B.SC., and Miss J. Pegg, B.SC. The duplication of the potassium estimations was done in the laboratory at the Sheffield Royal Infirmary (Dr. A. Jordan) by Mr. D. A. Podmore, A.R.I.C., Miss K. P. M. Groocock, B.SC., and Miss M. C. O'Connell, B.SC. The estimation of 17-ketosteroids was done by Mr. F. Mitchell, B.SC., in the laboratory of the Jessop Hospital for Women, Sheffield (Dr. G. C. Paine). To all these chemists my thanks are due. Dr. Harold Tulloh and Dr. Barbara Green, my house-physicians, and Miss L. M. Edwards, my ward-sister, gave me much help. I am indebted to the Medical Research Council for the A.C.T.H. and the cortisone.

THIOPENTONE FOLLOWED BY NITROUS OXIDE AND OXYGEN FOR ANÆSTHETISING OUTPATIENTS

E. Harvey Franks
M.B. Lond., D.A.
LATE RESIDENT ANÆSTHETIC REGISTRAR, BEDFORD GROUP OF HOSPITALS

UNTIL recently a blind eye was turned on the unsatisfactory conditions associated with general anæsthesia for ambulant patients. In no other type of anæsthesia were anoxia and poor operative conditions permitted, but in the casualty department these were looked on as inevitable. Bourne (1951) tried to prevent anoxia and struggling by using cyclopropane instead of nitrous oxide, and was impressed by the results. Rook (1952) emphasises the advantages of a short-stay ward attached to the casualty department; outpatients can then be given full premedication followed by adequate general anæsthesia. Franks (1952), however, points out that very few hospitals possess a short-stay ward, and that the length of stay in hospital required by this technique is a disadvantage.

In busy outpatient departments rapid recovery and early return home are outstanding considerations, and this is why nitrous oxide still remains the most commonly used anæsthetic agent for outpatients in this country. Though in many cases patients can be anæsthetised satisfactorily with nitrous oxide, in others it fails badly. In anæsthetic-resistant patients a smooth anæsthesia with good operative conditions cannot be obtained unless the gas-and-oxygen is reinforced or superseded by a more potent agent. It is over the choice of the potent agent that disagreement arises.

DISADVANTAGES

The disadvantages of various techniques of general anæsthesia for outpatients are as follows:

Nitrous Oxide—Air.—Adequate oxygenation cannot be maintained, and length of administration is limited.

Nitrous Oxide—Oxygen.—It may be impossible satisfactorily to anæsthetise resistant patients. Anoxia may be unavoidable.

Nitrous Oxide—Oxygen—Trichlorethylene.—This is a very useful technique but may produce breath-holding or a bout of coughing in heavy smokers.

Cyclopropane—Oxygen.—The main disadvantages of this method are that it is inflammable and cannot be trusted to the novice. Postoperative nausea and vomiting may be troublesome.

Intermittent Thiopentone.—Recovery may be slow and be associated with disorientation. The practice of shortening the recovery period by *routine* injection of an analeptic does not appear rational.

Full Premedication and General Anæsthesia.—A short-stay ward is essential, and the patient's stay in hospital is very long after even minor surgical procedures.

THIOPENTONE—NITROUS OXIDE—OXYGEN

Various methods of general anæsthesia have been tried in the casualty department of the County Hospital, Bedford, and that described below has been found the most successful. It is not a new technique; its use in resistant dental cases has been described by Macintosh and Pratt (1940). It has been used here in more than two hundred consecutive and unselected adult outpatients, and has shown its best results in the anæsthetic-resistant and in the poor-risk patients in whom anoxia is particularly undesirable. This method allows optimal oxygenation of the tissues and thus enables nitrous oxide to produce its best degree of muscle relaxation (Guedel 1951). It is assumed that, if 17–20% oxygen is administered throughout the major part of the anæsthesia, anoxia is either minimal or absent.

The method consists of a sleep-dose of thiopentone followed by nitrous oxide/oxygen anæsthesia. It is based on the synergistic action between these agents shown by Organe and Broad (1938), who observed that administration of about 85% nitrous oxide and 15% oxygen halved the amount of barbiturate required to produce anæsthesia.

Premedication.—Atropine gr. $^1/_{100}$ is used in all the cases to prevent excessive salivation and to reduce thiopentone-irritability of the larynx.

Assessment of Patient.—Each patient is classified according to age, physique, occupation, habits, &c., as "frail," "average," or "resistant," and the dose of thiopentone varied accordingly.

Sleep-dose of Thiopentone.—The amount needed by most patients is 2–5 ml. of the 5% solution (0·10–0·25 g). This amount is, of course, inadequate to produce anæsthesia. In making the injection 0·5 ml. is given and, after a slight pause during which the patient is asked if he feels any discomfort, the remainder of the selected dose is injected *rapidly*.

Inhalational Supplement.—As soon as the patient has become unconscious, several breaths of pure nitrous oxide are given, after which oxygen is introduced in increasing concentration. Gas-and-oxygen is administered for about two minutes before the operation begins, so as to produce some degree of nitrous oxide saturation in the tissues. After the skin incision, &c., the oxygen can usually be increased to, and maintained at, 17–20% without reflex movements or other signs of lightening anæsthesia. The Walton III machine has been used without rebreathing, the percentage of the inspired gases being read off from the dial directly.

Recovery.—Consciousness is regained well within a minute, but sometimes a patient appears to remain asleep at the end of this time; he will, however, open his eyes if addressed loudly and soon begins to talk rationally. There seems to be little tendency to fall asleep again unless the dose of thiopentone has been excessive. There is a striking absence of excitement on coming round. Nausea and vomiting are uncommon, as indeed are other ill effects. A few patients complained afterwards of headache, but in these the dose of thiopentone was probably excessive. Many patients remarked on the pleasantness of the anæsthetic. Most patients were able to leave hospital in about half an hour by public transport, often unaccompanied.

Range of Use.—The technique has been used for all the common outpatient operations, except those on the face. The length of the operations varied from $1^1/_2$ to 28 minutes. The technique is indicated especially in anæsthetic-resistant and poor-risk cases.

RESULTS

This method has been used in more than two hundred consecutive adult patients, and data have been collected in the last hundred of these. Of these hundred patients 14 were classified as frail, 71 as average, and 15 as resistant. Their ages varied from 18 to 89, and twelve patients were over 70. The average dose of thiopentone was 3·75 ml. of the 5% solution, with a range of 1·5–7·0 ml. Only 2 patients required more than 5 ml. The average oxygen proportion for the major part of the anæsthesia was 19%, and the average time to leave hospital was $28^1/_2$ minutes, with a range of 15–50 minutes. 55% went home unaccompanied and without incident. The post-anæsthesia vomit-rate was 6%. In no case was there regurgitation after the thiopentone. This was prevented by giving the patient's stomach plenty of time to empty before induction, by keeping his head slightly elevated on a pillow, and by using only very small doses of thiopentone. Operative conditions were excellent in most cases, and satisfactory even in resistant patients. Anoxia seemed to be either absent or only slight.

I wish to thank Dr. M. D. C. Hosford, consultant anæsthetist to the Bedford group of hospitals, for his very helpful

criticism and advice in the preparation of this paper; and the casualty staffs for their coöperation.

TETRAETHYL LEAD POISONING

REPORT OF A NON-FATAL CASE

GEOFFREY WALKER
M.B. Lond.
FORMERLY HOUSE-PHYSICIAN, PROFESSORIAL MEDICAL UNIT, MIDDLESEX HOSPITAL, LONDON

PHILIP R. BOYD
M.B. Lond.
SENIOR MEDICAL OFFICER, ASSOCIATED ETHYL COMPANY LTD.

THE following history is typical of tetraethyl lead (T.E.L.) poisoning.

The patient was foreman of a gang of men employed to remove the T.E.L.-containing sludge from large storage tanks which had contained leaded petrol, and although he seems to have been familiar with the stringent safety precautions required in such work he apparently omitted to observe some of them.

A brief account is also given of another five men similarly exposed to the same hazard.

CASE-RECORD

Case 1.—A man, aged 26, had cleaned petrol tanks since December, 1949. He worked about thirty-five hours each week with frequent short daily rest periods in the open air. Inside the tank he wore protective boots and gloves and an oilskin suit, but admitted that sometimes he had not worn the positive-pressure air-line respirator provided as an essential part of his equipment. He explained that it made manual work uncomfortably hot, and slower for his gang than his ambition to prove himself an efficient foreman would permit. He claimed to have observed all the other precautions required in his occupation, such as washing before meals and after work each day, bathing and changing his clothes regularly, and drinking a pint of milk each day; but he admitted that his unprotected face was sometimes splashed by the sludge. He was twice clinically examined by local doctors, on Aug. 24, 1950, and Feb. 12, 1951. On both occasions he was found healthy, and on the latter occasion was told that no signs of lead absorption were detected.

The following history was compiled with the help of the patient's diary. In early February, 1951, he first experienced difficulty in falling asleep and in concentrating on the administrative side of his work. He was worried about his wife's health and about debts resulting from excessive beer-drinking. Later the same month he abruptly stopped drinking. By March 9 he was so despondent that he decided to absent himself from work for a few days, but he was recalled the same evening. The next day he heard that one of his men had become insane; and on his own initiative he stopped work and took his men to London, where he reported to his employers. On March 11 the gang left for another site, and that evening he overheard the men debating whether or not to tell him of the sudden death of one of their workmates, allegedly from a brain tumour. They had apparently noticed that he was depressed and listless and did not wish to upset him further. He immediately became very anxious and wished to visit a church. Instead he went to see a doctor, who reassured him and sent him back to his lodgings. Anxious to be with his wife, who was then on holiday 100 miles away, he set out to walk to her, without any idea of the appropriate route. A lorry driver picked him up, soaked to the skin, and drove him to London, where he found his way to his own home. Subsequently he was taken by his wife to a hospital where, after an examination, he was reassured and sent home. On March 15 his employers, who suspected T.E.L. poisoning, arranged for him to be admitted to the Middlesex Hospital.

On admission he was obviously worried and talked about himself for two hours, quoting extensively and haphazardly from his diary. He was anxious about his wife's health, and explained that he felt that he was responsible for the death of one, and the illness of another, of his men by failing to insist on precautions which he had known were necessary in their work. He said that for 2 weeks he had experienced twitching of the nose, a feeling of something stuck in the throat, a creeping sensation in the region of the right ear and shoulder, transient blurring of vision, and episodes of what appeared to have been experiences of *déjà vu*. He had also had insomnia, relieved by hypnotics, for over 3 weeks, and since admission he had experienced panicky feelings of instability. He complained of halitosis and a metallic taste in his mouth for a few days. His appetite had become voracious, but he claimed to have lost about 14 lb. in weight during the last month. He had recently complained of a mild sore throat and occasional headaches but had had no fits or faints and no disturbance of bowel habit. The family and past medical history revealed nothing which seemed relevant.

On examination he appeared intensely anxious, but the physical signs usually associated with anxiety were strikingly absent. His temperature was 97·4°F; pulse regular, rate 68 per min.; and blood-pressure 105/45 mm. Hg. His palms were warm but dry; there was no tremor of his outstretched hands; and his pupils were not dilated. His tendon-reflexes were symmetrically brisk, and there was no "lead line." There were no other physical signs of disease, except a large blister on the left big toe—evidence of his long walk. He weighed 164 lb.

Examination of the blood showed Hb 13·3 g. per 100 ml., red cells 5,000,000 per c.mm., colour-index 0·95, white cells 7400 per c.mm. (neutrophils 45%, lymphocytes 44%, monocytes 5%, eosinophils 6%). No basophilic stippling of erythrocytes was seen.

Urine.—Tests for reducing substances, coagulable protein, and blood were all negative.

Lumbar puncture produced clear cerebrospinal fluid at a pressure of 105 mm. (rising freely to 185 mm. on jugular venous compression) and containing protein 30 mg. per 100 ml., sugar 61 mg. per 100 ml., chloride 692 mg. per 100 ml., and 1 lymphocyte per c.mm. A Pandy test was negative, and a Lange test gave 0000000000.

Liver-function Tests.—A colloidal gold test was negative. Thymol turbidity was 3 units. The serum-bilirubin level was 0·3 mg. per 100 ml. The alkaline phosphatase level was 2·7 King-Armstrong units, and the cholesterol level 174 mg. per 100 ml.

Urinary Lead *.—The corrected urine-lead levels were 0·36 mg. per litre on March 15; 0·24 mg. per litre on April 10; 0·23 mg. per litre on April 22; and 0·21 mg. per litre on April 23. The normal urinary excretion of lead is 0·06–0·08 mg. per litre (Kehoe et al. 1935).

Chest radiography and electrocardiography showed no abnormality.

Electro-encephalography and abdominal radiography are discussed below.

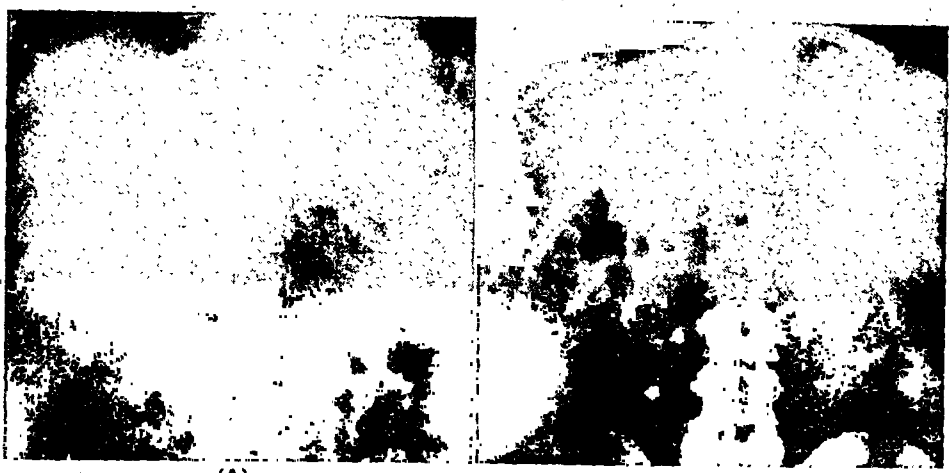
Treatment was entirely conservative. For the first week the patient was confined to bed, encouraged to drink five or six pints of fluid daily, and given phenobarbitone gr. 1 four times daily and 'Sodium amytal' gr. 3 at night. Subsequently he was allowed out of bed for progressively increasing periods, and the sedation was reduced. The phenobarbitone was omitted for two days before electro-encephalography.

Progress.—His symptoms gradually disappeared, and when he was discharged on April 14, 1951, he complained only of occasional creeping sensations in the right side of his head and insomnia when the sodium amytal was withheld. During his month in hospital he gained 10 lb. in weight, his pulse-rate was 60–80 per min., and his temperature 97°–98°F. His blood-pressure, known to have been 130/80 mm. Hg in February, 1948, averaged 90/50 mm. Hg during the first week, and increased to 120/60 mm. Hg on discharge.

Follow-up.—He was seen again on April 23 and 24, 1951, when he was admitted overnight for electro-encephalography,

---

* Lead estimations were done by a short colorimetric method using dithizone on snap samples of urine, and the values obtained were corrected to a standard specific gravity of 1·014 by multiplying by 14/X, where X equals the last two figures of the specific gravity of the urine when the specific gravity of water is expressed as 1·000. This method was adopted to obtain comparable figures over long periods in individual workmen when only snap samples were available. The values it gives are roughly proportional to the rate of excretion of lead.



(A) (B)

Radiograph showing liver shadow of (A) patient and (B) control.

and again about 3 weeks later, after a seaside holiday. At this time he said that he felt very well but still required a hypnotic at night. He proposed to look for alternative employment.

RADIOGRAPHIC DEMONSTRATION OF LEAD IN THE LIVER

T.E.L. is highly lipoid-soluble, and Kehoe and Thamann (1931) showed that in laboratory animals it is concentrated in lipoid-rich organs, particularly the liver. Cassells and Dodds (1946) confirmed this in two fatal human cases, reporting values of 2·35 mg. and 2·5 mg. of lead per 100 g. of wet liver tissue. At the suggestion of Dr. D. Sutton that such lead concentrations in the liver might be demonstrable radiographically, the patient and three healthy medical students of similar girth were radiographed with identical exposures, and the plates were developed under identical conditions. The patient's liver shadow was denser than that of the controls (see figure). That this difference can be due to the presence of lead in the liver was confirmed by taking radiographs, under identical conditions, of a glass tank containing water, and then an aqueous solution of lead acetate containing 2 mg. of lead per 100 ml. The shadow of the lead solution was appreciably denser than that of the water alone. Lack of other patients has so far prevented extension of this work.

ELECTRO-ENCEPHALOGRAPHY

Electro-encephalography on March 27, 1951, showed a slow α rhythm of 8 per sec., which was disturbed in all areas by runs of 5–6 per sec. waves, seen most obviously in the central part of the right temporal lobe. Hyperventilation caused the appearance of paroxysms of 2 per sec. waves in both frontal regions and some 3 per sec. activity over the rest of the cortex.

By April 24, 1951, the record had changed considerably, the dominant frequency varying between 7 and 9 per sec., its voltage having doubled from 16 to 32 μ. In the first record the recordings from the parietal region were relatively flat and featureless, whereas in this record the 7 per sec. frequencies were predominant. In the temporal lobes the previous asymmetry was reproduced and, as elsewhere, had a higher voltage. The response to hyperventilation was also different: within half a minute low-voltage 2 per sec. waves appeared in both occipital regions. High-voltage generalised 3–4 per sec. waves first appeared at $1^1/_2$ min. and appeared paroxysmally for the rest of the exercise of $3^1/_2$ min. and for 20 sec. after it. They had not appeared in the previous record until 2 min. 20 sec., and on that occasion were not nearly so well marked.

We have not been able to find any published work on the electro-encephalogram in T.E.L. poisoning in man; but Hill and Parr (1950) mention the unpublished finding that the changes resemble those seen in the early stages of T.E.L. poisoning in cats, which Steinman and Thorman (1939) describe as a decrease in amplitude of cortical rhythm, with a tendency to cortical instability. Our findings, which conform with these, suggest that in man T.E.L. causes generalised suppression of cortical activity, with the appearance of non-specific slow-wave activity.

DISCUSSION

The anti-knock properties of T.E.L. were discovered by Midgley and Boyd (1922), and manufacture and blending with petrol began in America in 1924. The toxicity of the substance was not recognised until many workmen died, when manufacture was suspended for a year, pending the result of a government inquiry. It was resumed only after the enforcement of strict industrial and medical controls which made the industry safe. There have been no deaths since manufacture and blending started in England in 1940. Apart from isolated cases, such as those reported by Cavallazzi (1946), where poisoning followed exposure to an insecticide, and those of Bini and Bollea (1947), where workers cleaning clothes with leaded petrol were involved, the only cases reported recently in America and Western Europe have occurred in tank cleaners. These men work in small parties and, in spite of supervision, have in each incident relaxed the precautions necessary for their safety. Such an outbreak in England was reported by Cassells and Dodds (1946).

T.E.L. is absorbed chiefly through the skin and the respiratory tract, and waterproof clothing and respirators of various types afford complete protection. Hence, when proper equipment is available and is in working order, tank cleaning should be entirely safe, outbreaks of poisoning being due to the negligence of the workmen.

The clinical picture of T.E.L. poisoning was reviewed by Machle (1935). The symptoms are referable chiefly to the nervous and alimentary systems. Insomnia, lassitude, irritability, and unpleasant dreams appear early, and may be followed by weakness, tremor, and headache. Anorexia and loss of weight are common, and nausea, morning sickness, and diarrhœa may occur. In severe cases a toxic psychosis develops, with hallucinations, delusions, and excitement which may terminate fatally in delirium. If recovery takes place it is usually complete, and sequelæ are uncommon. The characteristic physical signs are pallor without anæmia, low temperature, bradycardia, hypotension, and brisk tendon-reflexes. In severe cases collapse and encephalopathy are found. Lead line, neuropathy, and basophilic stippling of the erythrocytes are rare in contradistinction to inorganic lead poisoning.

The diagnosis is established from a history of exposure, the clinical picture, and urinary lead estimations. Mild cases give urinary concentrations of about 0·2 mg. of lead per litre, and severe cases up to 4 mg. per litre. The clinical picture, however, does not always run parallel with the urinary excretion of lead.

The most widely accepted treatment is conservative. Good nursing, sedation, and the maintenance of a high intake of fluid are essential. R. Kehoe (personal communication) states that there is little evidence that the course of the disease has been materially influenced by he use of dimercaprol. No results have so far been published on the effect of di-sodium phosphate, recommended by Proctor and Kahn (1950) to accelerate the excretion of lead in inorganic lead poisoning.

The development of symptoms within a few days of stopping heavy drinking of beer, noted in case 1, was also noticed by Benassi (1939) in his fatal case. No explanation is offered.

NOTES ON OTHER CASES

Case 2.—A single man, exposed in a similar fashion to case 1, after a few days of insomnia and restlessness, became confused, deluded, and aurally hallucinated, and was certified insane on March 9. On admission to a mental hospital his temperature was 97·6°F and his blood-pressure 105/80 mm. Hg. No physical signs of organic nervous disease were found, but moderate albuminuria and hæmaturia were present. His mental condition gradually improved, and he was fit for discharge after 6 months.

Case 3.—A man, who had twice sought medical advice for insomnia and weakness, collapsed on March 7 and was admitted to hospital. He was very agitated and complained bitterly of a sore throat, although only minor faucial injection could be seen. 2 days later he became hallucinated and increasingly restless and died after a convulsion. At the time of his death his occupation seems to have been unknown, and the diagnosis of T.E.L. intoxication was not considered. The history of exposure and the subsequent clinical picture, however, strongly support the possibility of T.E.L. poisoning, although confirmatory biochemical evidence is not available.

Three other men, who had minor symptoms of sleeplessness and restlessness but no physical signs, were found to have an abnormally large amount of lead in the urine and undoubtedly had mild T.E.L. poisoning.

SUMMARY

A non-fatal case of tetraethyl lead poisoning in a petrol-storage tank cleaner is reported, with notes on other affected men.

Observations are made on the electro-encephalographic changes and on the increased density of the liver shadow demonstrated radiographically.

We wish to thank Prof. A. Kekwick for his encouragement and permission to report the case, which was under his care; Dr. D. Sutton, who suggested and provided the facilities for the liver radiography; Dr. G. Parsons Smith, who interpreted the electro-encephalograms; and Dr. W. T. Earlam, under whose direction the urinary lead was estimated.

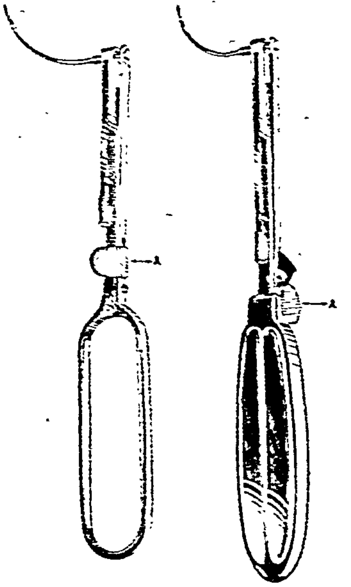
"Some people think that the philosophy a scientist accepts is not of very much importance: his job is to observe the phenomena. This is a gross oversimplification, and it involves the subsidiary hypothesis that all scientists are fully equipped with serendipity. A sensible philosophy controlled by a relevant set of concepts saves so much research time that it can nearly act as a substitute for genius; it may be that this is what we mean by genius. Thus equipped we avoid the pseudo-problems or, more correctly, the problems that are real in adjacent fields but pseudo in our own. A scientist can have no more valuable skill than the ability to see whether the problem he is investigating exists and whether the concepts he is using are applicable. But the lure of a concept that clarifies another field is strong and many of us follow it, like the music of the Pied Piper, to our scientific detriment."—N. W. PIRIE, F.R.S., *Science News,* 25, 1952, p. 20.

New Inventions

MODIFICATION OF BONNEY-REVERDIN NEEDLE-HOLDER

FOR the surgeon who uses the Bonney-Reverdin needle-holder, here is a modification which should be found useful. The essential difference is that the needle eye is opened by means of a separate press-button (shown at point A) instead of by compressing the handle.



The chief reason for altering this well-tried instrument is the tendency of the needle eye to be opened by accidental compression of the handle when the needle is being inserted in or withdrawn from tough tissues such as the rectus sheath. The needle either breaks or becomes fouled in the tissue and soon needs repair.

The two needle-holders shown are exactly the same except that one has a solid handle and the other a loop. They are made by Heaton Grogan Co. Ltd., of Clerkenwell.

Reviews of Books

William Smellie

The Master of British Midwifery. R. W. JOHNSTONE, C.B.E., M.D., HON. LL.D., professor-emeritus of midwifery, University of Edinburgh. Edinburgh: E. & S. Livingstone. 1952. Pp. 139. 20s.

FOUR boys destined to inscribe their names indelibly on the scroll of medical history were born within a period of thirty years and a distance of thirty miles of one another in the county of Lanark—William Smellie (1697), William Cullen (1710), William Hunter (1718), and his brother John (1728). Smellie is almost best known by the pithy and eminently quotable lampoons written by jealous colleagues. How many medical readers remember that he was said to have "monstrous hands fit only to hold horses," but can recall little about his great place in the history of obstetrics? He used his big hands most dexterously, and by his teaching and practice greatly helped to improve the conditions of poor lying-in women, and the clinical teaching of midwifery to midwives and medical students. This short biography is a modern assessment of his work. The author claims that no other man advanced in his lifetime the knowledge and practice of midwifery to an extent in any way comparable with that achieved by Smellie, and in circumstances which would have discouraged someone less heroic. Without powerful friends to help him, without the advantages of a hospital clinic, he attended and taught in the homes of the poor; and by so doing, and by his writings, raised himself to the foremost position in his profession. His case-notes are freely quoted. As the narrative proceeds, describing one difficulty after another, Smellie's personal character emerges. A man of good will, he was kindly and tolerant towards all except those who were pretentious, insincere, or false; and his unselfish devotion to his patients' interests and his great skill and thoughtfulness are recalled. The remarkable fortitude of his patients is astonishing. Indeed, to us, with our analgesics and our wide choice of anæsthetics, the sufferings which child-bearing women underwent in the 18th century whenever there was any obstetrical complication are almost unimaginable, and show the reasons that inspired James Young Simpson's unwearied search for a safe anæsthetic for childbirth.

The technical details in this important book will fascinate modern obstetricians and midwives, and there is much that will delight the ordinary reader.

An Explaining and Pronouncing Dictionary of Scientific and Technical Words

W. E. FLOOD, M.A., PH.D., lecturer in education (science method) in the University of Birmingham; MICHAEL WEST, M.A., D.PHIL. London: Longmans, Green. 1952. Pp. 397. 12*s.* 6*d.*

ILLUSTRATED with 1300 thumb-nail sketches and diagrams, 10,000 scientific and technical words in fifty subjects (including such things as building and architecture) are here explained as to a person knowing little or nothing about them. The idea is good but the execution poor. The selection of terms for explanation is uneven, with many omissions and some naïve and even unacceptable definitions ("dog watch . . . 4–6 evening, 6–8 morning"; "diptera . . . insects with two pairs of transparent wings"; "Chagas disease . . . carried by bed-bugs"; &c.). Moreover, the phonetic representation is irritating for two reasons: the accent does not mean that the syllable before it is accented but the syllable after it; and the letter R is entirely disregarded except when it comes before a vowel or H. On the other hand, this dictionary is a useful one to have on the shelf because it is likely to list words not contained in some other dictionaries.

The Art of Marriage

MARY MACAULAY, M.B., J.P. London: Delisle. 1952. Pp. 97. 7*s.* 6*d.*

THIS is yet another book in a field where supply must surely soon outpace demand. It is sensible and accurate, but adds to the long list of similar works which are neither exceptional nor exceptionable. The half-quotations from older books (extending as far as Ovid's *Art of Love*) which somehow stick in the mind of sex educationists are all here; so is a good deal of sound advice based on experience. The book has in it most of the factual matter which patients need, and it is at least fully convinced that sexual relationships can and should be pleasurable. For general counselling use it is probably fully adequate.

Medicinal Chemistry

(In 2 volumes.) ALFRED BURGER, associate professor of chemistry, University of Virginia. New York and London: Interscience Publishers. 1951. Pp. 1084. 80*s.* each vol.

THIS work surveys in detail the whole field of the chemistry of medicinal agents for the advanced student of this branch of chemistry or of pharmacology. Interested medical readers will find it full of information on the effect of chemical structure on pharmacological action.

After some general chapters Professor Burger deals with drugs grouped according to their therapeutic uses. Structural chemistry is presented in detail; syntheses and derivatives are given great prominence, derivatives especially being used to display the relationship between graded changes of molecular structure and alterations in therapeutic or other biological effects. Modes of action and metabolic fate are discussed and methods of testing outlined; but comments on therapeutic use are brief, and, on occasion, somewhat ill expressed. The major chapters—on such things as analgesics, drugs acting on the cardiovascular system, and antihistamines—are replete with formulæ of active substances, including all the newer derivatives. References, in footnotes, are ample (up to 1951). Some shorter chapters (those on parenteral fluids, expectorants, and antacids, for instance) are rather sketchy, being insufficiently backed with data from modern organic synthetic chemistry.

In the second volume, which deals with hormones and chemotherapy, the steroid hormones are described chemically in great detail, while sex-hormone therapy occupies less than a page. The sections on sulphonamides, antimalarials, organic arsenicals, antibiotics, and antiseptics are full of facts, and theories of their action are well discussed. Drugs used in the chemotherapy of tuberculosis occupy a 20-page section, and the chapter on antiseptics offers a complete survey and ends with a particularly full account of the quaternary ammonium compounds.

It is a notable achievement for a single author to assemble, in two compact volumes, such an enormous amount of relevant chemical information, and to present it in such a pleasing lucid style.

Surgical Gynecology

J. P. GREENHILL, M.D., professor of gynæcology, Cook County Graduate School of Medicine, Chicago. Chicago: Year Book Publishers. 1952. Pp. 350. $8.50.

IN his preface the author states that he has tried to show in as simple a way as possible how to carry out nearly all the gynæcological operations that are being done today. In this he has succeeded most admirably. His text is clear and his exposition definite. Over 100 beautiful pen-and-ink illustrations define each step in the various operative procedures. In addition to the usual operations associated with gynæcology, he describes how to repair injuries to the bladder, ureter, and bowel, and gives an account of the surgical treatment of hæmorrhoids and the repair of inguinal and femoral herniæ. Pitfalls and dangers are mentioned just where they may occur. The book has been carefully prepared and is suitably indexed. It is limited to its title and is not too lengthy. In a future edition the author might consider inserting on each plate of illustrations the name of the operation being described.

Diseases of the Heart and Circulation (2nd ed. London: Oxford University Press. 1952. Pp. 472. 35*s.*).—In its second edition, Dr. A. A. Fitzgerald Peel's useful students' textbook has undergone considerable revision, and—as too often happens with new editions—enlargement. It retains its original merit of correlating clinical cardiology with anatomy and physiology. Unfortunately, its approach to therapeutics is not so commendable. No attempt has been made to differentiate between the treatment of supraventricular and ventricular paroxysmal tachycardia; and to suggest that amyl nitrite may be of value as a hypotensive agent in hypertension is, to put it mildly, asking for trouble. It is unfortunate, too, that trade names for drugs should be used so profusely, when other teachers are striving to induce their students to restrict themselves to official or approved names. These are minor blemishes in an otherwise commendable book.

Autopsy Diagnosis and Technic (3rd ed. New York: Hoeber. London: Cassell. 1951. Pp. 471. 45*s.*).—The first edition of this book by Dr. Otto Saphir appeared in 1937, the second in 1946. It was written, in the form of a working manual, to provide a diagnostic outline of the gross lesions most commonly encountered at necropsy. Modifications of the techniques of Rokitansky and Virchow are well described and illustrated, while there is a special section devoted to the examination of stillborns and infants. The chapter on the necropsy permit shows the differences in law and custom between the U.S.A. and the United Kingdom, both in the ordinary and the coroner's examination. These differences—together with the American vogue for embalming the dead—account for the concern of the American pathologist to make use of limited and inconspicuous skin incisions. Dr. Saphir rightly charges the prosector, when he has completed his examination, with the task of explaining the clinical picture in the light of his findings, and of explaining in terms of morphology the various laboratory data collected during the patient's lifetime. The technical parts of the book are very good, but the accounts of the abnormalities found at post-mortem examinations are of questionable value for students, being given more fully in textbooks of systematic pathology. Those with some practical experience of necropsies who are revising pathology, however, may benefit from this form of presentation.

THE LANCET

LONDON: SATURDAY, SEPT. 6, 1952

What of General Practice?

To many students and young doctors the idea of going into general practice makes no notable appeal. For this there are many reasons; but commonly these include ignorance and prejudice. The medical student, trained in scientific method, naturally measures the general practitioner's opportunities by the precise yardstick of science—and shakes his head. What may escape him is that the good family doctor laces science's cold portion with the warmer stuff of humanism. Some of this humanism is being formalised in the doctrine of social medicine, which is finding its way into curricula; but, even so, the general practitioner's twofold technique remains essentially empirical, and only those who have tried know the difficulties and satisfaction of applying it. The ivory hospital of the medical school gives little clue to the medical life beyond its walls. As one practitioner puts it in a letter that we print this week:

> "There are many who can think only of the team around the bed in the great teaching hospital, where the personal onus of care is not so heavily on one man, where the relatives are not watching each move and action, and where the patient's friends do not have to be met and spoken to each day."

The student's prejudice against general practice derives partly from the influence of his teachers. Last week, in his good-natured tilt at academic training, Dr. Bromley [1] observed that this is the age of the medical don. Dons, especially those who pursue scientific disciplines, are not remarkable for their tolerance of the empirical; and thus, unknowingly, academic teachers may turn their students against a career beyond the university or large hospital.

The upshot is evident from an article that appeared a week or two ago in our unconstrained Points of View series. Here an anonymous correspondent [2] outlined in darkest colours his conception of general practice. Now others of his generation may not see the picture so black; but we believe that many see it in varying tints of grey. Our correspondent hinted at this. "So it is," he concluded, "that the queue for specialisation grows and grows, and those that at last sink into general practice are bitter and frustrated near-specialists, hating themselves and their job."

Such hostility is best eradicated by giving the facts; and an increasing number of medical schools are shrewdly enabling students to meet practitioners and to see practices.[3] The sort of information that such contacts may yield is indicated in the letters that we publish this week in reply to our correspondent's, perhaps deliberately, provocative arguments. Conditions for the practitioner are far from perfect; but they are not nearly so inimical as some have supposed. Together, these letters show that general practice is emphatically a live concern; and Dr. Ball suggests that the National Health Service Act, far from hastening its end (as many with keen *Schadenfreude* have proclaimed), has in some ways given it new strength. For example, the shadow of fees no longer inhibits doctor or patient; the heavy task of buying a principal's place no longer weighs on the young doctor; and clerical work is, if anything, lighter than before. Furthermore it seems that the rift between hospital and practitioner is being partly bridged by an increasing number of hospitals that are wisely opening their investigation departments to the family doctor, who thus retains more patients continuously in his charge. Then again, the Danckwerts award at last promises adequate pay. Though this alone will not bring suitable candidates, it is one important factor.

We believe that more good candidates will come forward—and come forward eagerly—if students are convinced of the importance of general practice to our society. Unfortunately, general practitioners, who already appreciate this, seldom say so—our correspondence columns this week provide a welcome exception. A college or faculty of general practice [4] could do much to attract to this indispensable and rewarding work a fair share of the profession's best skill.

Isoniazid Trials

A few weeks ago, discussing bacterial resistance to isoniazid, we suggested that there seemed no justification for using this substance alone in preference to streptomycin and *p*-aminosalicylic acid (P.A.S.), except in planned clinical trials.[5] Grace and his colleagues [6] now suggest that it should not be used alone even for large-scale clinical tests. As such tests are at present being carried out by the Medical Research Council in this country, by the Veterans Administration and the Public Health Service in the U.S.A., and by the National Association against Tuberculosis in Sweden, this view needs to be carefully considered.

The evidence on which it is based is derived almost entirely from laboratory experiments. Grace et al. point out that isoniazid is the only commercially available antibacterial agent, apart from streptomycin, against which bacteria can become almost completely resistant in a single step. Furthermore, in vitro, resistance to isoniazid originates about 1000 times as rapidly as resistance to streptomycin. The advantages of administering more than one antibacterial substance are evident in many diseases; and mutation to resistance against two drugs given together is theoretically the product of the individual mutation-rates. In the case of isoniazid and streptomycin it has been calculated that a volume of bacteria almost as great as that of the human body would be necessary for the finding of a cell simultaneously resistant to both agents. Grace and his colleagues predict the early and widespread appearance of resistant strains if isoniazid continues to be used alone, and this will largely neutralise "one of the most hopeful developments in the recent history of tuberculosis therapy"; trials of isoniazid alone are "nothing short of catastrophic."

[6] Grace, E. J., Bryson, V., Szybalski, W., Demerec, M. *J. Amer. med. Ass.* 1952, 149, 1241.

This argument seems to be based on several assumptions: that isoniazid is a very effective agent against tuberculosis in man, that resistance to it is clinically significant and permanent, and that combination with other drugs will prevent resistance. None of these assumptions has so far been proved. The original reports on isoniazid suggested that it is remarkably effective against tuberculosis in man; but this has not been conclusively demonstrated. Furthermore, the clinical significance of resistant strains emerging during treatment is difficult to determine. The emergence of variants highly resistant to streptomycin tends to worsen the prognosis; but strains of relatively low resistance may have little or no clinical significance.[7] Although highly isoniazid resistant strains can be produced in the laboratory, the resistance of strains so far reported in the sputum during treatment has been relatively low.[8] Highly resistant variants will probably be found as investigation continues, but it cannot be assumed that they will necessarily have the same significance as with streptomycin. Certainly there is already a hint that isoniazid resistance may be of some importance, since the number of bacilli in the sputum begins to increase after its appearance [8]; but this feature has been observed during streptomycin treatment, even when the variants which have emerged show such low resistance that this in itself may be clinically insignificant.[9] Furthermore, in vitro, resistance to isoniazid is certainly not permanent. Strains which appear resistant can become sensitive when grown in isoniazid-free media [10]—a reversion which does not take place with streptomycin-resistant variants. As Grace and his colleagues point out, there is still no indication that this reversion occurs in the body when isoniazid is stopped; but there is also no evidence that it does not occur. Very little is known about combinations of isoniazid with other drugs. Exposure of tubercle bacilli in vitro to isoniazid with streptomycin apparently delays or averts bacterial resistance to both [11–13]; but we do not know whether other combinations behave similarly.

In the absence of so many essential facts we cannot accept the conclusions of Grace and his colleagues. But, supposing that the dangers they foresee are real, can continuation of the trials still be justified? An effective, relatively cheap drug that can be administered for long periods by mouth would be of immense value. Treatment with streptomycin and P.A.S. is still expensive, and, except under close supervision, difficult to carry out in the patient's home. In large areas of the world the only chance of helping the great majority of patients is by developing a form of antibacterial therapy readily obtainable by all. It seems right, therefore, to explore fully the potentialities of isoniazid even in the face of early reports of bacterial resistance and knowledge of what this might signify. Without controlled trials of isoniazid alone the efficacy of this drug cannot be proved, nor can its effect be measured against the known action of others. The action of streptomycin and P.A.S. alone and combined has been fully investigated, particularly by the Veterans Administration in the U.S.A. and by the Medical Research Council in this country. Because of the planned continuity of the M.R.C. investigations it may perhaps be possible to compare the effects of isoniazid with those of streptomycin and P.A.S. alone and combined. Such basic knowledge would have much value. Grace and his colleagues suggest that administration of isoniazid should be combined with, for example, streptomycin and P.A.S.; but the immediate clinical effect of the three drugs together is unlikely to be much greater than that of streptomycin and P.A.S. only. Thus to show the differences convincingly would require very large numbers of patients with long delay in completing the trials. Moreover, the important question whether isoniazid can be used effectively by itself would remain unanswered. Only properly conducted clinical trials can quickly and convincingly prove that isoniazid should not be used alone. Warnings based on *a priori* reasoning are unlikely to prevent the widespread use of such a simply administered, cheap, and plentiful drug in a disease such as tuberculosis. Facts are required; and these can come only from efficiently conducted clinical trials.

At the same time, on the evidence so far brought to light, the potential dangers of bacterial resistance are real enough to justify a very strong warning against its indiscriminate use in ordinary practice, either alone or with other antibacterial drugs. Streptomycin and isoniazid together are already being investigated under controlled conditions, and we hope that isoniazid and P.A.S., which form an attractive combination because of its easy administration, will also be tested in this way. Until the results of these trials are known it seems reasonable to give it together with, rather than instead of, streptomycin and P.A.S. Voluntary restraint in the exploitation of this new and probably valuable drug can prevent any serious dangers from bacterial resistance.

Atropine Alkaloids

Physicians, no less than metaphysicians, must often wonder why the vegetable kingdom contains well-defined chemical substances with specific actions on man and animals—actions which can often be turned to good therapeutic account. Many vegetable drugs still hold their own. We are hard put to it to improve on morphine, ergometrine, digoxin, and emetine, to mention only a few. Pharmacists spend a good deal of time and energy (to say nothing of money) in trying to improve on Nature. Their purpose is to enhance the therapeutic usefulness of a drug and at the same time to diminish its side-effects. Whether they succeed or fail they usually throw new light on the action of the drugs they investigate.

The deadly nightshade, *Atropa belladonna*, is a good example. Some of its actions have been known for centuries, but modern developments in the chemistry and pharmacology of its alkaloids date from the isolation of atropine by Mein in 1831. The structure

of the atropine group of alkaloids offers almost unlimited scope to the chemist. They are esters formed by the union of an aromatic acid (tropic acid) with organic bases (tropine or scopine). The substitution of other acids and bases has yielded a crop of synthetic compounds, many of which have come to the notice of doctors in recent years. Yet, although many of these new drugs have established their claim to official recognition, the indications for their administration in preference to atropine or hyoscine are rather limited. Moreover, existing atropine substitutes are likely to be constantly challenged by new arrivals. Homatropine (tropic acid plus mandelic acid) has, however, almost certainly come to stay—at any rate among ophthalmologists—and in the United States eucatropine, the mandelic acid ester of a polymethyl piperidine derivative, is put to similar uses. Other synthetic compounds have been designed to give maximum relaxation of smooth muscle with minimum effects on the eye, the salivary glands, and cerebral function. One of this group is amprotropine phosphate (' Syntropan ') (the tropic acid ester of 3-diethylamino-2, 2-dimethyl-1-propanol), which is intended to relieve painful spasm in the hollow viscera—the intestine, bile-duct, bladder, and ureters. The structure of ' Trasentin ' is a new departure, for it contains neither tropic acid nor tropine, but retains simply the form of an ester and the tertiary amino base. Here again the aim is to produce an antispasmodic drug acting on involuntary muscle and having no perceptible effects elsewhere. In fashioning these new compounds to produce particular effects, chemists start from the fact that the activity of atropine on the autonomic nervous system is centred in the tropic acid radical, and that the tropine base is practically inert. The essential reaction that they use is the esterification of tropic acid with a tertiary amino alcohol.

The atropine group of drugs are thought to act on the effector cells in the distribution of the cholinergic fibres of the autonomic system by blocking the acetylcholine effect; but it is by no means certain that the same mechanism accounts for their action on the brain. The contrast between the effects of atropine and hyoscine on cerebral function suggests that their pharmacological actions can hardly be identical. Meyers and Abreu [1] have compared the central and peripheral effects of atropine, hyoscine, and some of the synthetic atropine-like compounds. They emphasise the importance of working on the living animal. In studies of the effects of the atropine group of compounds on the colon of the unanæsthetised monkey, they found that none of the synthetic drugs, except homatropine, compared with atropine in their ability to produce complete and sustained inhibition of motility of the large bowel. No-one would give these drugs by injection for their ocular effects, but it is of considerable academic importance that synthetic compounds which powerfully inhibit the alimentary canal were found to have a negligible effect on the pupillary reflexes. The action of these compounds on cerebration appeared to be biphasic, varying with the dose: small doses were apt to produce only lethargy; larger amounts were followed by hyperpnœa, excitement, motor weakness, and then drowsiness. Meyers and Abreu claim that doses can be chosen which produce a persistent excitement, lasting for as long as forty minutes in the case of hyoscine and for a shorter time in the case of the synthetic drugs. They emphasise that " except for differences in potency as shown by the different dose required to produce the same effects no differences between atropine and scopolamine were observed." The subject is complex and is full of pitfalls for those who attempt its simplification. Although atropine and scopolamine are known to act in the same way on the peripheral autonomic nervous system, there are quantitative differences and peculiar contrasts in regard to the susceptibility of various tissues to the effect of the two drugs. On the heart, intestine, and bronchioles atropine has a much stronger and longer action: on the other hand, scopolamine is a more powerful blocking agent for the iris, ciliary body, and certain secreto-motor fibres (sweat, salivary, and bronchial glands). In clinical practice one complicating factor is the biphasic character of the response. This depends on the concentration of the drug in the tissues; and thus very small doses may evoke actions which are the very opposite of those following large doses. This biphasic response has been carefully studied by Dr. W. F. Anderson,[2] whose work is particularly important for its emphasis on the fact that tissue cells exposed to attack by powerful drugs may react differently according to whether they are, so to speak, suddenly overwhelmed by a high concentration of molecules or, on the other hand, given time to adapt to solitary invaders. As regards the atropine group, the biphasic response was observed by Meyers and Abreu as an evanescent bradycardia, which they attributed to preliminary medullary stimulation; but usually this feature is likely to be obscured by the rapid onset of the drug's predominant action.

The newcomers among the atropine substitutes include ' Banthine,' which chemically resembles ' Panparnit ' and ' Trasentin.' Here the objective seems to have been to evolve a more satisfactory drug for the treatment of diseases of the alimentary tract accompanied by spasm. Chapman et al.[3] have carried out kymographic studies in healthy adults who had received 100 mg. of banthine. The effect was compared with that of tincture of belladonna; but it is noteworthy that the doses here were conservative—0·4 and 0·6 ml., equivalent to 0·12 mg. and 0·18 mg. of alkaloid. Banthine, it was found, caused a striking decrease in propulsive and total contractions and a slight to moderate decrease in tone. Banthine acted more rapidly and inhibited motility to a greater degree than did tincture of belladonna in either dosage. Chapman et al. observed more dryness of the mouth after banthine than after tincture of belladonna, and also tachycardia—which did not occur in the tests with belladonna. This contrast in side-effects again raises doubt as to the adequacy of the doses of belladonna. Banthine was used by Levy and Zweifler [4] in 100 cases of infantile colic and vomiting. The result was classed as good in 68%, as moderately good in 12%, and as poor in 20%. It would be interesting to know what results might have been obtained from doses of belladonna large enough to produce minor side-effects.

Annotations

DIURNAL EXCRETORY RHYTHM

Soon after birth a daily cycle of behaviour is established in relation to sleeping, waking, and feeding with subsidiary patterns of diurnal rhythm affecting other physiological functions. These include body-temperature, white blood-cell population in peripheral blood, carbohydrate metabolism, renal excretion of adrenocortical steroids, and renal excretion of water and electrolytes.

The excretory cycle of water and electrolytes has been known and investigated since 1877.[1] During the night there is a diminution in the renal excretion of water, sodium, potassium, chloride, and bicarbonate with a fall in urinary pH and a rise in urinary ammonia and titrable acidity.[2] In the morning there is an "alkaline tide" in the urine; this is unrelated to the gastric secretion of hydrochloric acid since it occurs despite achlorhydria or fasting. In addition there is a rising output of water and electrolytes, which reaches a peak about midday with a subsequent fall and a minimum output during the night. This complex cycle depends on fluctuations in renal tubular transfers of ions, since in the normal person there is little or no change in renal hæmodynamics (renal blood-flow and glomerular filtration-rate) or plasma-ion levels throughout the twenty-four hours.[3] While one might be tempted to ascribe the diurnal rhythm to a cycle of adrenocortical activity, as evidenced by diurnal variation of eosinophils in peripheral blood and of urinary excretion of adrenocortical hormones, the evidence is against this possibility.[4] The diminished pulmonary ventilation associated with sleep, and the resulting acidæmia, may be the factor determining the cycle of renal tubular function.[2] It is well known that, in acute experiments, hyperventilation and the resulting alkalæmia produce pronounced changes in renal ion clearances, though these are not quite comparable to the altered ion clearances brought about by waking.

Attention has lately been focused on the reversal of the diurnal rhythm of water and electrolyte excretion in congestive heart-failure accompanied by œdema and cirrhosis of the liver with ascites.[5] In such patients, however, it is noteworthy that there is an associated diurnal rhythm in renal hæmodynamics with maximum renal blood-flow and glomerular filtration-rate at night.[6] This may possibly be related to changes of posture or activity during the twenty-four hours. Such a renal hæmodynamics cycle, rather than an altered cycle in hormonal control of renal tubular ion transfers, may account for the reversal of diurnal rhythm of water and electrolyte excretion.

Our knowledge concerning the mechanism of the normal diurnal rhythm and its reversal in disease states is still incomplete. Will further research provide clues to that all-important problem—the unknown mechanism that controls the volume of extracellular fluid?

ADVANCES OF SCIENCE

Scientists must recall with sympathy the plight of that wrecked sailor who had so many things that he wanted to do that whenever he thought he would like to begin he couldn't, because of the state he was in. Luckily for us, or possibly unluckily, they have not stumbled on his masterly solution—which was to do nothing but basking until he was saved. Members of the British Association for the Advancement of Science, now meeting in Belfast, have so much to tell each other, and on such very different topics, that opportunities for basking must be strictly limited, despite the indulgent and excursive hospitality of their hosts, and the fact that the Mountains of Mourne are performing their well-known feat only a short drive away.

But, indeed, it is doubtful whether scientists are in the mood for basking. A hundred years ago their forerunners could carry their calling lightly, looking confidently forward to a benefited world. Today, as Prof. A. V. Hill, F.R.S., the president of the association, said of their ethical dilemma, "science finds itself unexpectedly and without those centuries of tradition and experience in a position no less important to the community than medicine: and its ethical principles have not yet clearly emerged." There seems, he concluded, to be no simple answer. Scientists are naturally as anxious about this as the rest of us; but they have accepted the duty of using their minds as well as they can to discover the nature of the universe, and like the rest of us they take refuge in their work.

Certainly they have plenty to occupy them. Their programme at Belfast contains no specifically medical section, but various sections touch on medicine—notably those on chemistry, zoology, physiology, psychology, and agriculture. Subjects of interest to doctors include such things as the control of the movements of the alimentary canal, the chemistry of bread-making, the assessment of personality, and Britain's food-supplies. In speaking of the problems of parthenogenesis, Prof. A. D. Peacock, D.SC., was not perhaps discussing a subject of immediate concern to us, but he raised some interesting speculations. In the last year, he recalled, G. Pincus and his associates have been responsible for the development of seven rabbit parthenogones; all were female, five were born alive, and one has since produced a litter of nine after normal mating. Pincus sees a possible application of the principle in stockbreeding: if cows could be made to breed females by parthenogenesis it would be extremely convenient.

VALVULOTOMY VERSUS SHUNT

Cyanotic congenital heart-disease is nowadays treated surgically in centres all over the world as a result of the pioneer work of Blalock and Taussig[1] in Baltimore. Because these unfortunate patients can now be relieved, partly or completely, of their disabilities, interest has quickened greatly. The rapid advances in such techniques as cardiac catheterisation and cardioangiography have made it possible to reach an accurate preoperative diagnosis in almost every case; but there remains the question of which operation will afford the best result.

The shunt operation of Blalock is ideally suited to cases of severe pulmonary atresia or of tricuspid atresia. Pure stenosis of the pulmonary valves, however, clearly invites a more direct approach to widen the stenosed opening; and this Brock[2 3] has most successfully practised. The problem now before the cardiologist and cardiac surgeon (for it is imperative that they work together) is which patient will derive most benefit from a subclavian-pulmonary anastomosis, and which from a direct valvulotomy or infundibular resection[4] of the stenosed area. Pure pulmonary valvular stenosis (i.e., not associated with an interventricular septal defect) is best treated by Brock's direct attack on the stenosed opening with a valvulotome.[5 6] A Blalock shunt is contra-indicated since sooner or later right-sided heart-failure develops because the strain on the obstructed right ventricle is unrelieved. On the other hand, with atresia of the tricuspid valve so little blood enters the right ventricle that this is largely functionless, and pulmonary valvulotomy will be useless. In such patients

venous and arterial blood are mixed in the left ventricle and only an anastomosis between the systemic and pulmonary circulations—i.e., a Blalock or Potts operation—will allow the blood to enter the lungs and so relieve the cyanosis. Possibly there is one other group in whom a shunt type of operation must be carried out—those with such extensive pulmonary atresia that direct attack is impracticable.

Between these two groups of cases, in which the indications for either a shunt operation or valvulotomy are fairly precise, there lies a large number in which the decision may be difficult. Where a surgeon is more experienced in arterial anastomosis, he will naturally find himself treating most of his patients in this way. Others will favour the direct relief afforded by valvulotomy, and as they gain greater experience in its execution will find more cases to which it can be successfully applied. A recent report by Brock[7] is particularly illuminating. Of his first 223 cases of pulmonary stenosis, 112 were treated by anastomosis and 111 by direct operation; but in the first 50 there were 2 direct operations and 48 anastomoses, whereas in the last 50 there were 36 direct operations and only 14 anastomoses. Of these 14, 5 were cases in which a direct operation could not be done for reasons stated above.

The direct relief of pulmonary stenosis seems, therefore, to be technically possible in about two-thirds of the cases. It is certainly an attractive solution, since it largely restores to normal the mechanics of the heart, adds no new strain, and does not call for an artificial ductus with its potential risk of infection. Nevertheless only continued close study of patients treated by these alternative techniques will establish their relative values.

GETTING INTO STEP

THOSE of us who find irksome even the mild regimentation of contemporary civilian life will readily sympathise with the soldier who is "out of step." Usually he is a young man who finds that soldiering does not agree with him and that the consequences of kicking over the traces of discipline can be more unpleasant in the Army than in civil life. He may have wanted to be a driver, not an infantryman; if he could not be a driver he wanted to transfer to the Navy or the Mercantile Marine. He, and his like, find it hard to conform. They have not learned to swallow small injustices, and they almost inevitably run foul of the authority of the orderly room; and their "crimes" may range from personal neglect ("dirty rifle") to absence without leave. Sometimes their offences, though still not of a kind to get them into real trouble in civil life, are more serious and may vary from making Donald Duck noises on parade to throwing a bucket of whitewash over the regimental sergeant-major.

In 1941 the Army established at Pontefract a camp at which the training was to be "specially framed with a view to reclaiming young soldiers from a career of crime and converting them into good soldiers." Mr. Joseph Trenaman, who shared in the educational side of the venture, has described[8] the men who came to the camp, and how they fared there. Physically the men were weaker, feebler, and more ill-nourished than the ordinary run of young soldiers. They were a little below the average level in innate intelligence, but not obviously subnormal; emotionally they were immature. For the most part they came from poor and overcrowded homes. Only some 14% had been apprenticed to a skilled trade in civil life, and many had been in police trouble there; 36% had been convicted of indictable offences before joining the Army. But Trenaman believes that parental neglect was the "probable major factor" responsible for delinquency, with psychopathic states a poor second. Among the minor factors he lists, in order, physical deficiency, poverty at home, broken home, and invalid parents. Sir Cyril Burt, who contributes a stimulating preface to the book, does not like the term "psychopathic." It was a label bestowed by the psychiatrists who saw the men; but, as Burt says, different psychiatrists interpret the term in different ways.

Not all the men were enamoured of the new venture. It would have been overoptimistic to have expected otherwise. Some made it plain that they took a poor view of this latest outcropping of reforming zeal. The Glasgow youngster was probably not alone when he wrote across one of the early questionary forms, "none of your bissness." But the important thing is that the method seemed to bring results. The records of these lads were much better after treatment in the unit than they had been before.

ISOTOPES IN BRITAIN

DURING the late war British scientists heard with admiration—and not a little envy—of the remarkable developments in America as radioactive isotopes became available for biological research. These developments flowed directly from the brilliant work by American physicists in setting up cyclotrons and the first chain-reacting pile. After the war came a period when the United States with great generosity provided British workers with supplies of isotopes and information about the technique of their use in biological research. But these supplies were necessarily limited and could not in any case include the shorter-lived isotopes. It was therefore a great relief when the pile at Harwell came into action and home supplies were to be had. Now a wide range of isotopes can be obtained by British workers, and in addition Harwell carries on a thriving export trade.

With several years' experience now behind them, British workers can give a good account of themselves, as is shown by an issue of the *British Medical Bulletin* devoted to this subject.[1] A comprehensive review of this sort provides an opportunity for assessing the value of this fascinating and still novel application of physics to biology and medicine. The tale of what has so far been achieved has to be set against a background of the many technical problems that had to be overcome before any results at all were possible. Although nearly all isotopes are now prepared by neutron bombardment of suitable material in the pile, the actual production and isolation of each one involves an individual problem if material of the desired specific activity is to result. Isotopes are only useful to the biologist if they are present in the chemical form which he requires. For this reason the radiochemical centre at Amersham was set up. Here the necessary chemical manipulations can be carried out on highly radioactive substances: the compounds which the centre can supply include some forty labelled with C^{14}. In the subsequent handling of radioactive materials stringent precautions are needed, according to the type of radiation and the half-life of the isotope concerned.

In the measurement of radioactivity in tissues or whole organs there are many pitfalls for the unwary. The research-worker has to adjust himself to the new habits of thought required for the interpretation of experiments involving isotopes. He first has to become used to the idea that all his measurements are subject to an inevitable (but always calculable) error due to the random nature of atomic disintegrations, over and above any errors which may result from his manipulations. Then he must realise that his measurements only enable him to follow the fate of a small parcel of labelled atoms, introduced into his biological preparation at a particular time; rapid passage of a batch of labelled atoms through a given organ does not necessarily mean that large quantities of the corresponding unlabelled substance are passing through that organ all the time. A small sample of raw material may pass rapidly through a factory and be converted into the finished product; but if raw material is scarce the factory's total output may be low. Again, compounds neatly labelled by the introduction of a radioactive atom may be introduced into the body; but it cannot be assumed that the label will remain permanently in place. Finally a careful watch must be kept on the radiation received by the tissue under study, lest radiation damage should vitiate the result.

---

[8] Out of Step. JOSEPH TRENAMAN. London: Methuen. 1952. Pp. 223. 21s.

[1] *Brit. med. Bull.* 1952, 8, no. 2–3.

The technical and intellectual difficulties involved in work with isotopes are formidable: the compensating advantages are equally great. Where conventional chemical methods are too inaccurate or too laborious, or insufficiently delicate, isotopes often make possible an estimation that could not otherwise be effected. Studies on the metabolism of penicillin and vitamin B_{12} (described by E. Lester Smith) and on antigen-antibody reactions (A. Wormall) are good examples. Isotopes are particularly useful (as A. Neuberger shows for various proteins) in determining the average length of stay of the various component parts of large molecules incorporated in animal tissues. Then again, isotopes can be used efficiently in combination with another modern technique—paper chromatography. Gross and Pitt-Rivers demonstrate this elegant method in identifying a new iodine-containing compound in the blood of patients treated with radio-iodine.[2]

Thus isotopes make possible a new and more refined biochemistry, which is already reaping its harvest in many other fields. They can be used, for example, in clinical investigation, as C. H. Gray shows in his review on porphyria. But isotopes do not merely replace or extend chemical tests. They can be used, for instance, to label red blood-cells as well as molecules, and thus facilitate the estimation of blood-volume (E. B. Reeve). They can be used in conjunction with histology to show the location of elements within tissues (S. R. Pelc and A. Howard). Perhaps the most striking departure from traditional methods is in the detection and measurement of γ-emitting isotopes by external counters. Measurement of thyroid function in this way (described by N. B. Myant) may become a routine clinical test for thyrotoxicosis. The rate of disappearance of radiosodium, or its appearance elsewhere, after injection into the tissues or blood-stream, can give valuable information about rates of movement of ions into and within the blood (H. Payling Wright, E. M. McGirr) and even about the viability of the plastic surgeon's skin grafts (J. N. Barron and N. Veall).

Therapeutically, isotopes have great possibilities in the destruction of unwanted tissue. If that tissue is presented with a radioactive substance which it specifically concentrates, it can be bombarded from within, without risk to other tissues. Unfortunately this condition is still fulfilled in only a few instances. The thyroid gland is the clearest example. As E. J. Wayne and others show, thyrotoxicosis can be successfully treated with radio-iodine. The same is true of those thyroid cancers which concentrate iodine, though the differential concentration is nothing like as great as in thyrotoxicosis, and therapeutic bombardment is consequently more difficult to achieve (R. Paterson and others). The presentation to cancerous tissue in general of an effective isotope in a chemical form which would be concentrated specifically is very much in the minds of those working on the subject, but its achievement is not yet in sight. For the present we must be content with bringing the radioactive material into as close contact as possible with the tissue which needs to be destroyed. This has been done with some success in the case of bladder tumours by introducing balloons containing solutions of radioactive sodium or bromine (R. J. Walton and W. K. Sinclair). Some relief can be achieved in malignant pleural and peritoneal effusions by partial replacement of the fluid with suspensions of colloidal radio-gold.

In summary, the isotope technique has already made major contributions to fundamental biology. It is proving useful in clinical investigation and has had sufficient therapeutic success to justify hopes of better things to come. Owing to the technical complexities and health hazards, the handling of isotopes is best left to research-workers for the time being. But it is well that the rest of the profession should know what is going on in this field, for the potentialities of the method are so great that its applications might, in the future, be the concern of us all.

STREPTOCOCCI AND RHEUMATISM

THE generally accepted view that recent streptococcal infection is the underlying bacterial cause of acute rheumatism leaves unexplained many of the baffling problems in this group of diseases. Clinically acute rheumatic fever resembles serum sickness quite closely, and many workers have suggested that the clinical features of rheumatic fever are due to an antigen-antibody reaction at special situations in the body.[1] This hypothesis has been too vague to carry us very far. Many different kinds of antigen have been tested, ranging from streptococcal "toxins" to hypothetical antigens from the patient's own tissues; and lesions resembling those of rheumatism have been produced by various experimental procedures. But there is still no really convincing explanation of the specificity of the lesions or the relative parts played by the streptococcus and the patient's own tissues in determining this specificity.

Dr. Glynn and Dr. Holborow have investigated these problems in some new experiments, which they describe in this issue. It is now recognised that the specificity of a protein can be profoundly modified by chemical combination with non-protein substances known as haptens. By suitable combination of a bacterial protein with, for example, a polysaccharide, a new antigen can be created which has the specificity, not of the original protein, but of the polysaccharide which has been attached to the protein. Glynn and Holborow, using β-hæmolytic streptococci (group A, type 4) as source of bacterial "protein" and a solution of chondroitin sulphate from human costal cartilage as polysaccharide, prepared a chondroitin sulphate streptococcus vaccine. Rabbits received intravenous injections of this vaccine, a control vaccine of the same streptococcus not treated with chondroitin sulphate, and a solution of the chondroitin sulphate alone. Five out of six rabbits which received the chondroitin sulphate streptococcus vaccine showed evidence of joint lesions—some with acute synovitis—and the serum of all these animals gave a positive precipitin reaction with chondroitin sulphate solution. Control rabbits that received either the streptococcal vaccine or the chondroitin sulphate alone showed no comparable joint lesions, and neither these nor normal rabbits showed any precipitin reaction with chondroitin sulphate.

The combination postulated by Glynn and Holborow may possibly occur in a slightly different way: instead of the streptococcus providing the protein and the patient's tissues the hapten, the rôles may conceivably be reversed and the streptococcus provide a hapten which converts tissue proteins into "auto-antigens" with a new specificity. There is some experimental support for this concept. For example, Goebel and Avery[2] showed that a pneumococcal polysaccharide which acts only as a hapten when injected into rabbits can be made fully antigenic by conjugating it artificially with a suitable protein, whereas a pneumococcal polysaccharide which is non-antigenic when injected into rabbits is fully antigenic by itself in mice and men.

[1] See Fischel, E. E. *Amer. J. Med.* 1949, 7, 772.

[2] Goebel, W. F., Avery, O. T. *J. exp. Med.* 1931, 54, 431. Avery, O. T., Goebel, W. F. *Ibid*, p. 437; *Ibid*, 1938, 58, 731.

The discovery of the dramatic effects of adrenocorticotropic hormone has given a new impetus to the study of the rheumatic diseases; and the possible interrelation of hormonal factors, of the allergic state, and of an extrinsic bacterial agent poses some intriguing questions. The experiments described by Glynn and Holborow are interesting and suggestive; and we hope that these will be followed by further work on similar lines.

SEX-HORMONE METABOLISM IN LIVER DISEASE

CERTAIN clinical manifestations of liver disease have been thought to result from altered intrahepatic metabolism of steroid hormones with consequent disturbance of the normal balance between œstrogens and androgens.[1] In the male the most important clinical features of this sort are gynæcomastia, testicular atrophy, and loss of libido. Cutaneous spider nævi, palmar erythema, and loss of hair on the chest have also been attributed to a similar mechanism. Experimental data leave little doubt that the liver plays an important part in inactivating œstrogen; and observations in the rat have shown convincingly that this function may be impaired by malnutrition.[1] On the other hand, it now seems doubtful whether these results apply to other species. Zondek and Brzezinski,[2] for example, found that inactivation of œstrone was unimpaired in women with severe vitamin-B deficiency, while Hooker et al.[3] found that in primates the result of intrasplenic implantation[4] was the same as with administration by any other route. Direct evidence of hepatic inactivation in man has, however, now been described by Evans et al.[5] 9 patients receiving œstrogen therapy for carcinoma of breast or prostate were chosen because of their high blood-œstrogen levels. These levels were determined in samples taken simultaneously from the hepatic vein and the femoral artery. In 6 cases evidence of significant inactivation by the liver was detected. In the 3 cases where inactivation was insignificant the patients were severely undernourished.

Several attempts have been made to establish by assay of the hormones in the urine that such conditions as gynæcomastia arising in chronic liver disease result from impaired hormone metabolism. Rupp and his colleagues[6] found an increase of urinary œstrogen in 16 out of 25 cases of hepatic disease with gynæcomastia, but the over-all correlation was poor. Dohan et al.[7] also found no apparent correlation between the severity of the hepatic disease and gynæcomastia, or between gynæcomastia and the absolute values of urinary œstrogens. A further study of this problem by Dohan and his colleagues[8] provides, however, a possible explanation of such inconclusive results. 17 men with diffuse liver disease and 5 normal controls were included in this study. The severity of the disease was assessed by clinical examination, liver-function tests, and biopsy specimens. Hormone excretion was estimated on specimens of urine collected over several days, to minimise errors due to daily fluctuation; the estimations included the free and conjugated forms of œstradiol, œstrone and œstriol, and gonadotropin, all by biological assay, while total neutral 17-ketosteroids were estimated by a colorimetric method. Increased excretion of total œstrogen and decreased output of ketosteroids and gonadotropin was found to run approximately parallel with the severity of the disease. Urinary œstrogen was significantly correlated only with the serum-bilirubin and bromsulphalein retention—i.e., with tests of excretory function. Presumably the decreased ability of the diseased liver to excrete œstrogens accounts for the increased output by the kidney. The liver's ability to conjugate the steroids with glycuronic acid is apparently unaffected, since the increase of the combined form of the hormones in the urine is usually far greater than that of the free forms. The total œstrogen excretion, and still more the œstrogen-ketosteroid ratio in the urine, were significantly greater in the four cases with stable gynæcomastia than in those with regressing breast changes or no such changes at all. Dohan and his colleagues emphasise the importance of differentiating cases with persistent gynæcomastia from those in which the breast changes are reverting to normal, and suggest that failure to mark this distinction is the cause of previous failure to establish the relationship between the breast enlargement and the level of circulatory hormone as assessed by urinary excretion. The only test that could be correlated with spider nævi was that of free œstriol excretion; but a highly significant relationship was found between testicular atrophy with loss of libido and decreased excretion of gonadotropin.

These results confirm what has long been suspected, both on clinical grounds and from experimental work—that hormonal imbalance may result from impaired metabolism of hormones by the diseased liver. Excess of œstrogens is the most conspicuous result; but androgens may also be affected—a disturbance indicated by impotence associated with a fall in ketosteroid excretion due, at least partly, to diminished secretion of gonadotropin by the pituitary.

DEATH AFTER INOCULATION

MAINLY as the result of mass immunisation, begun in 1940, the extinction of diphtheria is in sight; and whooping-cough is now the most formidable acute specific respiratory disease of infants and very young children. A similar campaign against this disease, although long delayed by the need for large-scale controlled trials of vaccines made from numerous strains of *Hæmophilus pertussis* by different techniques,[1] is now in progress, and many thousands of children have already been inoculated without untoward effect other than an occasional transient local or general reaction caused by sensitivity to proteins of the dead organisms from which the vaccine is prepared. It is therefore disconcerting to learn of an inquest on a 2-year-old child who developed an abscess in the right upper arm after a second prophylactic injection of a whooping-cough vaccine and who later died of septicæmia—a sequel unique in the experience of the medical witnesses.[2] Since eight other children were inoculated with the same batch of vaccine, apparently without ill effect, the vaccine itself is clearly exonerated. Anyhow the tests for sterility by the manufacturers of this and other biological products for injection are so stringent that contamination of the contents of an ampoule before it is opened is extremely unlikely. At the inquest a pathologist expressed the opinion that death resulted from an accidental skin infection. Nevertheless, this tragedy should cause all who have to give parenteral injections to look to their technique.[3] The potential danger of infection of the needle-puncture from pyococcal skin lesions should also be borne in mind; and if such lesions are detected, prophylactic injections should be postponed.

Public Health

THE NEED FOR AN OCCUPATIONAL HYGIENE SERVICE

PETER H. NASH
M.A., M.D. Camb., D.P.H.
SENIOR CLINICAL ASSISTANT, SLOUGH INDUSTRIAL HEALTH SERVICE; LECTURER IN INDUSTRIAL PHYSIOLOGY, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

OCCUPATIONAL hygiene is the measurement of the industrial environment and its effects on workers' health. Though the advantages of this approach to industrial health problems have been appreciated in this country for many years, almost nothing has been done to apply it on a large scale. In the development of our industrial health services the emphasis has been on factory inspection—largely from a safety point of view—on the one hand, and health care by industrial medical officers on the other. In these aspects of occupational health, and also in factory legislation and notification of occupational disease, we have been pioneers and still have probably the finest services in existence. Unfortunately this is not true of our occupational hygiene facilities. Indeed no service of this kind exists and our country lags behind others.

AMERICAN PRACTICE

In the United States industrial health services developed rather differently. The great increase of production during the first world war resulted, as here, in outbreaks of industrial disease. To combat these, individual States set up divisions of industrial (or occupational) hygiene, usually as a branch of the State public-health department. These developed greatly between the two wars and now most States, and even some cities, have such divisions. They are based on a laboratory where physicians, engineers, chemists, and industrial nurses work together on occupational health problems. Each specialist lends his particular skill to the task. For example, a visiting factory inspector or nurse may be the first to discover a possible toxic hazard. The physician may then visit the factory and, by studying the environment, talking with management and workers, and making clinical and laboratory examinations of those likely to be affected, decide whether a health hazard exists. Chemists and engineers then survey the factory, taking air-samples in different parts, and measure the amount of toxic substance present in the air. If a health hazard is discovered the correct preventive action can be determined in the light of the known facts. In this the engineer, with his special knowledge of exhaust ventilation and other protective devices, plays a large part.

These laboratories carry a full range of equipment for assessing most physical hazards in industry. Thus they are able to analyse air and body-fluids for toxic substances, to perform dust-counts and analyses, measure radiation, and conduct lighting and thermal comfort surveys. An important point is that they are not organised for research, though research is of course done. Their main work is to help and advise industry in health. Much of the work is routine—for instance, repeated examinations in lead-works of air-samples, and urine and blood specimens. In this country there are no facilities for regular surveys of this kind, apart from blood-counts, except where the firms provide them. The occupational hygiene division also acts as an advisory centre on all matters of occupational health. Help is given to firms which wish to start their own medical services, and there is often an industrial nursing consultant who acts as focal point and adviser to all industrial nurses in the area.

Many other countries have developed such services —e.g., Canada, Finland, Peru, the Philippines, Sweden, the U.S.S.R., and Yugoslavia.

A FIRST STEP

I believe that there is a real need for a service of this kind. Anyone with access to a large number of factories, as we have at Slough, must come to realise that there is a great deal of occupational ill health which is never recognised, let alone notified. Through ignorance dangerous solvents and other toxic substances are used carelessly, and may cause disease which long remains undiagnosed. Men are also often exposed to high concentrations of the less dangerous solvents, and minor health impairments or worry over the effect of the fumes may lead to loss of production. Fettlers and grinders may work in confined spaces with high dust-concentration, their only protection a calico mask which they are expected to wear continuously. Often lighting, heating, or ventilation is poor, and recurrent though preventable eye injuries are found.

These situations arise because managements of small firms are not in a position to obtain advice on health matters. When advice is given in convincing form, they are usually anxious to coöperate and improve working conditions. A detailed survey of conditions, from medical and engineering aspects, figures for air-concentrations, and suggestions for action are far more effective in producing a positive response from management than mere verbal arguments.

The Factory Department of the Ministry of Labour and National Service has 16 medical inspectors of factories who are responsible for the whole of England, Scotland, and Wales. These inspectors have a wider knowledge of occupational hygiene than anyone else in the country, yet they have no technical assistants and no suitable laboratory behind them. Samples for analysis are sent to the Government Laboratory and, because only occasional samples can be analysed, few, if any, complete and repeated occupational hygiene surveys can be made. The situation would be very different could there be many more medical inspectors and regional laboratories, with engineers and chemists, to help them. The Medical Research Council's Unit for Research in Industrial Medicine has a fine laboratory and is able to undertake any kind of factory survey, clinical or environmental. It, however, exists primarily for research—and rightly so—and cannot carry out routine work or cope with the many small problems that exist up and down the country. Really serious hazards—such as instances of beryllium poisoning or the recent outbreaks of poisoning by dinitro-*ortho*-cresol—are dealt with immediately and effectively, yet the multitude of smaller problems cause greater loss of health and production.

Realising the need for this preventive approach to occupational health, the Nuffield Foundation and those working at Slough were responsible, in 1949, for sending an engineer, Mr. R. J. Sherwood, to Harvard to be trained in occupational hygiene techniques. After his return a small team was formed, consisting of myself as physician, Mr. Sherwood as engineer, and Miss Joan Bedford as chemist, to investigate occupational health problems at Slough and elsewhere. The foundation made a grant towards an occupational hygiene laboratory which has been set up at the London School of Hygiene and Tropical Medicine. Samples collected in the field are brought to this laboratory for analysis, counting, and so on. The laboratory is part of the occupational health sub-unit which also plays a part in teaching students of the D.P.H. (industrial elective) course and public-health engineers.

The number of requests for help which we have received has been greater than so small a unit can cope with. As well as the regular work at Slough on the discovery and control of toxic hazards, skin irritants, and uncomfortable working conditions, there have been requests for advice from managements who were about to instal new processes or who wished to check safeguards which they had installed. We have also had many calls for advice from industrial medical officers or direct from managements of firms in all parts of the country. Our experience has convinced us of the need for a service which can give technical help to industrial medical officers and, even more, to firms with no medical care. An occupational hygiene service to cover the entire country would need perhaps six or eight units, staffed with doctors, engineers, chemists, and physicists. If any industrial health service was later set up these centres could form an integral part of it.

A NATIONAL SERVICE

A precedent for these centres already exists in the Public Health Laboratory Service, which is administered by the Medical Research Council. There are 18 special or reference laboratories and a further 49 constituent laboratories in different parts of the country. Nothing like this number of occupational hygiene centres would be needed, but their administration by the Medical Research Council for the Ministry of Health following the pattern of the P.H.L.S. is a possibility.

There is also a strong case for the centres to become part of the Factory Department of the Ministry of Labour and National Service. This department has the necessary experience and a corps of medical inspectors who could act as leaders of the project. Further, the work of the service would be largely inspection, using every available scientific means, rather than research.

Another possibility is that industry itself should be encouraged to set up these centres. The National Coal Board, for instance, is already doing, and planning to do, preventive work based on research carried out by the Pneumoconiosis Research Unit of the Medical Research Council. The Industrial Hygiene Research Laboratory of Imperial Chemical Industries is an example of what a single large firm can do. Other large firms might do the same, but in many the hazards are not numerous enough to warrant such provision. Some industrial organisations, such as the Shirley Institute (cotton), the British Cast Iron Reserach Association, and the British Iron and Steel Research Association, already carry out some occupational hygiene investigations, though they are not primarily interested in health. Some of them are associated with the Department of Scientific and Industrial Research, which suggests the possibility of a combined private enterprise and Governmental approach.

Finally, some universities might consider it of value, from the point of view of teaching, to join in work of this kind, perhaps in coöperation with another agency such as the Factory Department. But whatever the form of organisation chosen, it is important that something should be started now. The health of our workers and the output of our factories should no longer be allowed to suffer for want of reasonable facilities in occupational hygiene.

I should like to place on record the names of those who foresaw the need for occupational hygiene at Slough and elsewhere in this country, and were responsible for sending the first engineer to train under Prof. Philip Drinker at the Harvard School of Public Health. They are Dr. A. Austin Eagger, Prof. J. M. Mackintosh, and Dr. M. E. M. Herford.

Poliomyelitis

In the week ended Aug. 23 notifications (uncorrected) of poliomyelitis in England and Wales were as follows (figures for the previous week in parentheses): paralytic 152 (170); non-paralytic 68 (88); total 220 (258). This brings the total for the 34 weeks since the start of the year to 2388, compared with the following totals for the same period in each of the five previous years: 1951, 1747; 1950, 4125; 1949, 2033; 1948, 1067; 1947, 3619.

According to the Weekly Epidemiological Record, issued by the World Health Organisation, there has been a definite recrudescence of the disease in Europe, and notably in parts of Western Germany, the Netherlands, and Belgium. In the U.S.A.[1] 2648 cases were reported during the week ended Aug. 9; this was an increase of 15% over the figure for the previous week. Up to Aug. 9 the cumulative total for the "disease year," which began with the week ended April 5, was 12,046; the corresponding figure last year was 7056. The incidence has also been increasing in Canada, particularly in the west, where quarantine restrictions have been imposed at two large military stations, from one of which 17 cases had been reported.[2]

International Certificates of Vaccination

The International Sanitary Regulations adopted by the Fourth World Health Assembly come into force on Oct. 1. New and simpler forms of certificates of vaccination against smallpox and cholera will then be used.

Persons going abroad, who are vaccinated against these diseases *after* that date, should have their certificates on the new forms, obtainable from the company arranging their passage. International certificates for vaccination done *before* that date remain valid for the period shown on them.

The international certificate of vaccination against typhus has been abandoned, because this vaccination is no longer required internationally.

Medicine and the Law

Murder and Abnormality

There is notoriously an unbridged gulf between the forensic and the medical view of insanity in relation to criminal responsibility. Two recent cases in the Court of Criminal Appeal show afresh how far the two are apart.

On the appeal of J. H. Godar,[1] convicted of murdering Maureen Cox, his counsel, Mr. G. D. Roberts, Q.C., conceded that at the trial the summing up had been full and fair and that there had been evidence on which the jury could properly find a verdict of guilty; in other words there were no grounds for an appeal. It appeared that Godar had in 1944, while serving in the Army, been found to be suffering from a disease of the mind amounting to defect of reason. This fact, however, was not mentioned as a matter for the appellate tribunal to consider; it was merely referred to by counsel, in passing, as one which the Home Secretary might perhaps take into account when advising the Crown as to the exercise of the prerogative of mercy.

On the other appeal, that of J. T. Straffen,[2] the apparent irrelevance of the appellant's mentality was even more striking. At his trial there had been evidence of his having been certified a mental defective, of his having formerly been found unfit to plead to a criminal charge, and of his having strangled two other little girls in addition to the 5-year-old Linda Bowyer whom he was accused of having murdered.[3] The Court of Criminal Appeal was not asked to note his obvious abnormality; it was irrelevant; the two grounds of appeal (technical questions of the admissibility of evidence, legally, no doubt, of great importance) ignored it. Even had the case found its way up to the House of Lords, his mental condition would still doubtless have been immaterial. Public opinion, as well as medical science, may be convinced of the irresponsibility of men like Straffen. The criminal law goes on its majestic way unconcerned.

"There are," wrote the late Sir Edward Troup, a former head of the Home Office, "a certain number of borderline cases in which the question whether a prisoner is insane,

4. *Ibid*, Aug. 21.
5. *Lancet*, Aug. 2, 1952, p. 239.

though negatived by the jury or not raised at the trial, has to be considered after conviction." If medical experts then certify the prisoner insane, "there is a consensus of legal authority for the view that it would be contrary to the common law to allow the execution, and the records which go back to 1840 show no exception to this rule." Accordingly on the advice of his panel of doctors the Home Secretary has recommended that Straffen should be reprieved. Thus, in the end, the medical opinion prevails over the judicial sentence after all. Sir Edward went on to give statistics showing that, over the 22 years from 1901 to 1922, out of 585 persons convicted of murder 517 were found to be insane, either before trial or by special verdict of the jury or on Home Office inquiry after conviction. If, as is probable, more recent totals show a not dissimilar proportion, is it not time for another review of insanity in relation to crime such as that which the Atkin Committee conducted thirty years ago? As Sir Russell Brain, P.R.C.P., has pointed out [6] the circumstances in which mental illness should mitigate criminal responsibility "is a question, not for lawyers or doctors, but for society to decide"; and he, too, thinks the question should be reconsidered, perhaps by a Royal Commission.

Points of View

CURE OF TOBACCO-SMOKING

LENNOX JOHNSTON
M.B. Glasg.

"How can I stop smoking?" I, who stopped many years ago, have often been asked. "By not smoking again," is the brutal correct answer; for every movement of smoking is voluntary. "But I have tried repeatedly and failed; I haven't enough will-power. Is there a way in which I can be helped to stop?" "Yes, there is a way," is the answer; and the purpose of this article is to show it.

The view that smoking can be stopped only by the exercise of will-power is almost universally accepted. Yet it is only part of the truth. For "knowledge is power" (or will-power) when acted upon. The greater the volume and more impressive the character of knowledge, the more insistently does it demand effective expression (in action). When knowledge is repressed, or is merely expressed in words unsupported by actions (when, for example, a smoker says, "I *know* that smoking is harmful" but continues to smoke), the power of knowledge is insufficient (usually because of insufficiency of knowledge) to compel its effective expression.

The urge to smoke is at first purely psychological —a desire. While it remains so, it is easy to give up smoking. As smoking proceeds, however, the urge becomes increasingly compulsive: the psychological urge has been reinforced by a pharmacological urge, the craving for tobacco.

PSYCHOLOGICAL URGES TO SMOKE

The desire to smoke originates from the advocacy of smoking by smokers, much of it unconscious. Each time a smoker lights up, he says in effect, "I am in favour of the smoking of tobacco, I approve of smoking"; and little weight attaches to any mere words he may utter in contradiction to his actions. Each proferred cigarette, each word of approval of smoking, written or verbal, is smoking propaganda. Every smoker is, in fact, whether he wills it or not, a living advertisement for tobacco, and there are so many smokers today, and they smoke and speak encouragement to smoke so often, that the persuasive pressure on non-smokers to commence or recommence smoking is powerful indeed. To this must be added the lavish scientific advertising of the tobacco combines. In the United States of America in 1945 it was calculated that almost 3000 non-smokers start to smoke every day.[1]

The initial desire to smoke is closely associated as a rule with one to appear grown-up or sophisticated, to imitate someone admired—usually Daddy or, nowadays, Mummy—or to be companionable or sociable. Later there is a recurring desire to perform the now largely habitual and often ritualistic actions of smoking, particularly at certain times—e.g., after meals—or to relieve boredom or nervousness. Freud drew attention to the possibility that oral-libidinal satisfaction—the association of smoking with the infantile pleasure of suckling—may also urge people to smoke.[2]

Psychological "infection" of the non-smoker is completed, as a rule, by the intimate persuasion of a smoker: "have a cigarette, old man"; "it'll do you good (or steady your nerves)"; "don't be so miserable (or a cissy)"; "one has to have a bit of pleasure (or comfort) these days"; or "one has to have one little vice; it doesn't do to be too good." Besides simple persuasion, reinforced by example and free samples, smokers use —though as a rule without realising it—less ethical methods of infecting non-smokers. Thus they suppress the facts, particularly the more damning facts, against smoking, and circulate in their place favourable untruths: in short, they use deception.

PHARMACOLOGICAL URGES TO SMOKE

Having established, on myself and 35 volunteers, that the repeated administration of nicotine is a satisfactory substitute for tobacco-smoking,[3] I decided to ascertain how long craving for a drug of addiction takes to develop.

> I was at that time somewhat addicted to nicotine, so I had to use another drug. I gave myself hypodermically, night and morning, cocaine hydrochloride, a drug I had not taken previously, in doses ranging from $^{1}/_{4}$ to 1 grain (16–64 mg.). About 5 min. after administering each dose, I experienced a curious sensation which I find impossible to describe: it was readily distinguishable from nicotine and codeine (whose actions are equally indescribable), but was not pleasurable. This occasioned me and a control volunteer to whom I administered several doses, some surprise—and, indeed, disappointment, for we had recently had considerable pleasure from experimental doses of nicotine. About 10 days after commencing the administration of cocaine, I found myself looking forward to the next dose with considerable satisfaction, and after 25 doses deemed it advisable to discontinue the experiment lest I became strongly addicted.

The slight craving I had acquired lasted several days, and could readily be recalled in fantasy for a much longer period. It must have developed as a side action of cocaine, and been built up cumulatively. With the craving came pleasure on its appeasement; and it seems clear that the pleasure derived from drugs of addiction arises mainly from the appeasement of craving, once such craving has been acquired. Pharmacological craving is clearly a specific, abnormal appetite for a drug, hostile (because of the drug's toxicity) to the normal, though not to the abnormal, functioning of the organism. Its development completes a vicious circle: administration gives rise, though not immediately, to craving, which leads to further administration. Once set in motion, this circle continues to turn without, as a rule, interference from the smoker's will.

Besides appeasing the craving of addicts, drugs of addiction have a further immediate specific pharma-

3. Johnston, L. *Lancet*, 1942, ii, 742.

cological action on both addicts and non-addicts. Smokers do not enjoy the pharmacological action of tobacco smoke at first—indeed, they usually dislike it. But as time goes on they find that, besides deriving positive pleasure from the appeasement of their craving, they have, if they be inhalers, an almost instantaneous general analgesic against life's little, or even big, stresses and vexations. The inhalation of cigarette smoke in moments of severe stress, in fact, is reminiscent of the inhalation of gas-and-air by a woman in labour. In pipe-smoking, the analgesic (or sedative) effect is delayed for about 10 minutes, since the absorption of nicotine is mainly alimentary. Unfortunately, the pleasurable analgesic action of nicotine (and of other drugs of addiction) is more than offset by after-depression and apathy. This cannot, of course, be demonstrated, since changes in mood are subjective; but I have observed that a striking and sustained uplift of spirits and of general interest almost invariably accompanies the giving up of smoking; and that heavy smokers seem as a class more depressed ("fed up") than non-smokers.

The effects of the psychological and pharmacological urges cannot be separately demonstrated, nor can their relative strengths be measured; only their combined effect on conduct is obvious. But interrogation of (I estimate) about 10,000 cured smokers over the past 24 years, and a personal analysis based on stopping smoking four times (twice experimentally), and on taking some 200 doses of nicotine by various routes, have convinced me that the pharmacological craving for tobacco though strongly compulsive, at first, is short-lived, at any rate in its acute form. It reaches its peak 24–36 hours after smoking has been stopped and thereafter sharply and steadily declines, though the initial steepness of the decline is not maintained: it takes several months, indeed, to reach zero.

Psychological urges to smoke, on the other hand, do not decline steadily when smoking is stopped, since most of the psychological stimuli which produce them persist. In my case, the desire for the general analgesic action of nicotine persisted, in times of particular stress, for more than a decade; so also did the less compulsive urge to smoke for companionable reasons. The desire for a plaything—the wish to perform the habitual actions of smoking—scarcely troubled me, and could in any case have been almost completely satisfied by performing the actions of smoking without actually lighting the cigarette. The longing of the recently cured smoker, after a meal, is not to perform the habitual actions of smoking, but to administer his postprandial dose of nicotine.

If, after he has smoked for some time, the smoker loses desire to smoke, and wishes to stop smoking, a conflict develops between opposing urges—the will to stop smoking, on the one hand, and craving for tobacco reinforced by various psychological urges, on the other. If the smoker's will prevails, smoking is cured temporarily or permanently. If, however, his involuntary urges prevail, he continues to smoke; but his smoking no longer expresses his will. He therefore tends to repress the whole conflict, for the outcome has been damaging to his self-esteem. He attributes his smoking solely to socially approved urges such as habit, the relief of boredom, or a simple desire for enjoyment. Smokers who have tried unsuccessfully to stop smoking, though they seldom realise or admit it, are unwilling smokers.

All smokers, willing and unwilling, however, encourage the spread of smoking and add to tobacco consumption. This has risen in Great Britain from 166 million lb. in 1913, costing £8,300,000, to 281 million lb. in 1948, costing £42,800,000. The increase in smoking has resulted in the progressive elimination of one non-smokers' sanctuary after another—drawing-room, bedroom, work-room, place of entertainment, conveyance, and finally, of late years, hospital ward and sanatorium, even when and where patients seriously ill from respiratory diseases are under treatment. The problem of sanctuary for those who claim (as I do) that the right to breathe clean air—air free, at any rate, from irritant fumes—is as basic, in a civilised country, as the right to drink clean water, has become today almost insoluble even when they are ill.

HOW TO STOP SMOKING

It is difficult to stop smoking—very difficult indeed if one is a heavy smoker of long duration. In order to stop, it is necessary to do much more than merely decide. Intellectual conviction that smoking should be abandoned is an essential preliminary, of course, to stopping, but it is only a preliminary. There must also be a build-up of resolution sufficient to withstand indefinitely all urges to smoke. As in war, the more overwhelming the preparatory build-up of strength (or resolution), the easier and more certain the victory; and conversely, irresolution tends to prolong the struggle and jeopardise success. Resolution not to smoke is born, as already indicated, of a sound and clear, though not necessarily extensive, knowledge of the action of tobacco smoke on the human organism.

The most difficult task, as a rule, is to make the break—to withstand the first surge of craving. Half the battle is over when the first day and night of non-smoking are completed. It is best, in my experience, to stop suddenly, abruptly, completely, ignoring all symptoms which might possibly be associated with tobacco deprivation. Detoxication, and hence improvement in health, begin directly smoking is discontinued, no matter how the smoker may feel; so he must follow his purpose without regard to his feelings. All thoughts about smoking should be rigorously excluded from consciousness, because craving precludes, for a time, objective thinking on this subject. It may help if he treats the craving contemptuously from the start, by carrying for a time (while resolution runs high) the paraphernalia of smoking. The more inflexible the determination to end smoking, the less the pain: as in grasping nettles, pain varies inversely with firmness. It is well to proceed silently, unobtrusively: the raillery of smokers is shrewdly calculated to undermine resolution. Acute affections, particularly respiratory affections, temporarily remove or greatly reduce all urges to smoke. A good time to stop, therefore, is when such an affection develops; or respiratory inflammation may be produced artificially, to some extent, by smoking very heavily the night before.

Psychotherapy consists in building up the patient's determination to end smoking by persuasion, encouragement, undeception, and re-education—patient and oft repeated when necessary—until, in favourable cases, its expression in non-smoking becomes irresistible. Fear, particularly of lung cancer (though this is a long-term risk) can be a potent psychotherapeutic agent, and the use of such intimidation is clearly justified when—as in this case—it is based on fact, or at any rate strong probability. A first, often difficult, task is to dispel defeatism born of previous, sometimes repeated, failure—failure almost invariably associated with ignorance of essential facts about smoking. Friends ought perhaps to be warned against irritability; but I believe I displayed none, and I suspect that it may in some cases be "laid on" by the smoker in the hope of getting his wife or fiancée to entreat him to recommence smoking, and thus shoulder some of the blame for relapse.

Unless psychotherapy has been extremely thorough, there is great risk, with so much psychological infection about, of relapse, particularly at times of lowered resistance—e.g., on sociable occasions, or in moments of stress. To avoid this, it is best to go over to the offensive: the oftener and the more remorselessly one attacks the smoking of others and exposes the falsity of arguments in favour of smoking (while doing one's best to avoid giving offence), the more finally is one committed to non-smoking, and the less one's danger of relapse. As cure is consolidated, and understanding of the harm caused by tobacco-smoking deepens, there develops gradually and unconsciously a hardening of one's attitude, or even hatred of tobacco-smoking, with pity for tobacco-smokers.

THE TOBACCO TABOO

Smokers dislike contemplating the ill effects of smoking, for some of which they cannot escape responsibility—the ash, the ends, the fumes, the fires, and the damage to the health, happiness, and economy of individuals and nations. They tend to repress them, and hence dislike hearing them spoken of. Thus they discourage serious discussion of the subject, imposing, in fact, a "drug taboo." Those who, in defiance of the taboo, speak out about the ill effects of smoking, are disapproved, derided, or ostracised in proportion to their outspokenness. Public lectures, including radio talks, which give *without compromise* the medical facts about tobacco-smoking are unheard of. The more winged the phrase, the more pointed the argument against smoking, the less the chance of their publication in the press. Even the medical press shows reluctance to publish uncompromisingly anti-smoking matter. The most remarkable manifestation of the tobacco taboo is the omission from all standard textbooks on medicine of any account of nicotinism.

SMOKERS' UNTRUTHS

Smokers' untruths are not as a rule intentional—they are rationalisations rather than lies, and are the more deceptive on that account. Moreover, liberties taken with the drug taboo, like those taken with sex and religious taboos, are a fruitful source of humour. Jokes about alcohol are, of course, legion, but there are also many about tobacco: references to cigarettes as "gaspers" or "coffin-nails" are examples. Most of us, hearing little about smoking except this language of untruths and jokes, grow up ignorant or deceived about the facts, and are psychologically infected by nicotinism in our 'teens or before.

After smoking has started, the development of craving for tobacco is evidenced not only in increasing application to the drug, but in increasing resistance to undeception. As a result, confirmed smokers are often largely inaccessible to the facts against smoking: the simple deception which took in the "pre-smoker" becomes, with development of craving, an increasingly fixed delusion of the smoker. But the inaccessibility varies. Some smokers are almost wholly inaccessible, refusing to concede the validity of even the most obvious fact against smoking; others listen with full attention, and concede verbally even the most hostile facts. Unless, however, words are supported by deeds, the sincerity of such agreement must always be in doubt. The fixity of smokers' delusions is doubtless related to the strength of their craving for tobacco, and in many cases this is so strong that the smoker projects his repressed self-criticism on to his would-be undeceiver, characterising him as a crank or fanatic, or at the least, as hopelessly biased.

Smokers usually refer to tobacco as something good or desirable which adds to the joy of living—not quite a necessity, but at any rate a luxury. Officially it is treated, in fact, almost as a necessity: even when our shipping position was at its worst during the war, space was found to bring us huge quantities. Yet tobacco is not a luxury; even on addicts, the whole action is not luxurious: coming out of their drug, smokers are depressed, like addicts of other drugs. If tobacco is a luxury, opium is an even greater luxury, and has an even stronger claim to be treated as such. Actually tobacco smoke contains various poisons, notably nicotine, pyridine bases, carbon monoxide, and arsenic,[4] and it is clearly asocial to pretend this toxic drug is a beneficent luxury. Addiction to tobacco, like addiction to opium, is a specific disease—an intermittent intoxication. An almost universal delusion is that smoking is a vice—a moral, not a medical, issue. Vice (or moral degeneracy) is merely a symptom common to all drug addictions. It is revealed in the common disregard of smokers of the moral rights of non-smokers. I have been in homes where the feeding and clothing of the children were deplorable, yet the parent or parents spent relatively large sums (perhaps £1 a week out of a weekly income of £7) on tobacco.

A common minor delusion of smokers is that they get their pleasure from purely psychological factors—playing with the cigarette or lighter, sucking the pipe or watching the smoke. Smoking, they say, is not enjoyed in the dark, or by the blind. In fact, of course, smoking in darkened cinemas is widespread, and the blind are just as strongly addicted to tobacco as the sighted. An undeniable advantage of smoking is its sociability; but actions which are sociable are not necessarily social. "Thick as thieves," we say, meaning, I take it, that thieving is often sociable; but it is also asocial, like drug taking.

The symptoms of tobacco-smoking become apparent to the sufferer only after the disease has been arrested, and he has given up smoking. An accession of high spirits, energy, appetite, and sexual potency, with recession of coughing, makes the chief symptoms of tobacco-smoking plain. Moreover, an increase in weight, often measurable in stones rather than pounds, in the course of a few months, shows that tobacco-smoking usually interferes with nutrition—a fact which should be sufficient in itself to cause smoking to be forbidden in sanatoria.

Tobacco-smoking is not, of course, usually a seriously incapacitating or a directly killing disease; but that does not mean its effects on health are negligible. Its protracted course, the enormous numbers affected, and spreading infection make smoking one of our most serious diseases. The extensive published work on tobacco-smoking as a predisposing cause of other disorders has recently been reviewed by Scott.[5] Wynder and Graham,[6] and Levin, Goldstein, and Gerhardt,[7] in America, and Doll and Bradford Hill[8] in this country, have established a strong probability that the development of carcinoma of lung is favoured by tobacco-smoking, and this probability was strengthened by the observations of Dungal.[9] Deaths from carcinoma of lung have risen from 612 in 1922 to 11,272 in 1949—a rise of 1740% in twenty-seven years, or 64% per annum. The work of Pearl[10] shows the total effects of smoking on mortality. Smokers of ten or more cigarettes a day aged 30–45 have a mortality from all causes considerably more than double that of non-smokers. This heavy toll of human life at a comparatively early age has not been sufficiently recognised.

These facts have failed to stir our profession to action. The reason is not far to seek: about 80% of us, I estimate, are smokers, and we behave collectively like an addict of tobacco. Radical cure of tobacco-smoking lies in its prevention; and tobacco-smoking is no more difficult to prevent than opium smoking. Our duty is plain.

In England Now

A Running Commentary by Peripatetic Correspondents

"THEY order this matter better in France." What it was that was better ordered Sterne does not tell us, but I think I have found an answer.

Large numbers of the French embellish my practice. I really mean embellish, for consultations with that race are strenuous, exciting, even explosive, but never dull. I count among my most valued patients an ancient wrinkled peasant woman, equipped with all the shrewdness and capacity for clear thought which springs so naturally from the soil of France.

She complained that things did not march' as they should over the last few years. A lack of energy, not much, mais quand même. A certain slowing of the tempo of life of the most mysterious. What could it be, one asked oneself?

At the end of the consultation I found myself somewhat embarrassed, and glad that I had to talk in French. I am less easily understood in that language, and I did not want to be understood too easily. A puzzled expression rested on her brow as I haltingly fished from the corners of my memory words sufficiently vague to suggest without saying outright that after four score years it is the nature of things to feel a little less energetic than in the past: that at times we might even, without alarm bien entendu, experience a passing weakness.

Weakness! That did it. By sheer luck I had the right word, a word which could partner the ailments of the young as well as of the old. Her face lit up, as only the face of a Frenchwoman can when an explanation strikes home and her mind is set at rest. "Oui," she said with great satisfaction, "C'est ça. C'est la grande faiblesse. Voilà!"

I felt in my own mind an answering echo to her satisfaction. Who would mind suffering from la grande faiblesse? I feel I could even die of it in the grand manner, calmly and with dignity. But to succumb wretchedly to its English counterpart—what would it be, senile debility?—perish the thought.

That is at least one of the things they order better in France. They ennoble the commonplace with a gracious dignity of expression mixed with a sense of the dramatic. I wish I had had to write a certificate for the old lady. No printed slip for her! A grand flourish with a goose-quill on the finest parchment—that alone would have been fitting.

* * *

The children—not mine unfortunately—found a fledgling thrush fallen from the nest. They fed it on worms which it engulfed greedily; but, as so often happens, the ungrateful bird died untimely, mysteriously and undiagnosed. The case did not come to autopsy, but a conference was held to consider in what respects therapy had been inadequate. "I know what we ought to have done," said Bridget. "We ought to have chewed the worms first." Next time she will, for she's a kind girl to birds, though perhaps less so to worms.

* * *

Having recently had occasion to inquire into the possibility of purchasing some electrical apparatus, we found ourselves led insensibly into a series of communications with an old-established French firm. Our latest receipt in this correspondence is a schedule entitled *Conditions de vente*, which appears to contain the nub or crux of the projected transaction. It is a complicated document, and after several pages concerned with such matters as *expédition*, *délai*, &c., we came at last to the vital factor of *prix*. This factor proved unexpectedly difficult to elucidate, being surrounded by a scientific smoke-screen of Gallic exuberance and plasticity. The section began forbiddingly:

"*Nos prix sont révisables suivant la formule*

$$P = P_o\left(0{,}10 + 0{,}80\frac{S}{S_o} + 0{,}10\frac{M}{M_o}\right)$$

où les différents paramètres sont définis ainsi :— . . ."

But we are made of stern stuff, undaunted by income-tax schedules and claims for mileage allowance; dragging to our bosom our invaluable New Little Larousse, we ploughed on. It appeared that P was the definitive price, P_o the estimated price, S the index of wages in the Electrical and related industries published (and rectified globally) by a mysterious body designated R.G.E. two months before the actual date of delivery, and S_o the index for the fortnight preceding the date of the estimate. M_o was the price of aluminium in sheets of 1 mm. (R.G.E.), and M the value on the last day of the first two-thirds of the actual delay in delivery. When we had got thus far our attention was distracted by a musical plash, and we observed with interest that a drop of sweat from our overheated brow had fallen on the paper. All we had wanted originally was a galvanometer, but we no longer felt the desire.

On the other hand, when we showed the document to one of our clinical colleagues who is still fortunate enough to have a few private patients he was at once interested, and he has produced a sliding scale of fees based on a similar principle. His final charge (F) is related to the estimate given to the patient (E) by the following equation:

$$F = E\left(0\cdot1 + 0\cdot5\frac{C}{C_o} + 0\cdot2\frac{P}{P_o} + 0\cdot2\frac{T}{T_o}\right)^n + \sqrt{D_c.D_w}$$

where C is the mean cost-of-living index in the period between the operation and the rendering of the account, and C_o the index figure at the time of arranging admission. P and P_o represent the corresponding figures for the cost of petrol, and T and T_o those for telephone rental. D_c and D_w represent physical depreciation of our colleague and his wife in units of earning and coping capacity respectively, and the exponential n has been added by a statistical friend who feels vaguely uneasy without it.

* * *

Readers of the *Britannica Book of the Year* for 1951[1] must prepare for a serious shock when they turn to the section headed "Words and Meanings, New." If they can support "depurged" for "one restored to acceptable political or other standing," and are able to picture their charlady as an "accommodater"—surely the gracious old word "obliger" should be retained?—they will still have to face a shocking debasement of the term "bogey." This noble description of a golfer's performance stands, in this country, for the perfect score for a hole; and a "birdie," of course, describes a hole done in one less than bogey, while an "eagle" is reserved for the rare feat of doing a hole in two under bogey. Now, it seems, our golfing colleagues in the United States have begun to apply the noun "bogey" to a hole done in one over par (par being the perfect score for the hole), while double-bogey is used for two strokes more than par: and what is worse, they also use these terms as verbs. At this corruption of long-accepted usage we can only shake grave heads.

* * *

On stopping in our local mountain hut the other week-end for sodden sandwiches and cold tea, we found the following entry neatly written in purple ink in the visitors' book:

"I hitch-hike from my home in Spa to Ostond, then in the steamer I came to Dover, then again I hitch-hike to Birmingham, Glasgow, Aberdeen, and Balmoral, where it was raining much. There as I standed in the downpour I saw your [illegible] Queen, who smiled and waved to me, yes to me, a poor [illegible] wet tramp, as she drive to the church, and I could [illegible] 'Good morning.' I am quite comeover. Now I am in this hut for two nights and I have no food and still it is raining [illegible] much, and I am off to Aviemore. God bless [illegible] this hut; God bless your beautiful Queen; God bless the whole British people."

The hut is situated in one of the remoter fastnesses of the Cairngorms, and is reached by a mountain path strewn with large boulders, liberally interspersed with bog and torrent. In these days of [illegible] pessimism, and complaint, we feel that our [illegible] visitor's exuberant good will in the face of [illegible] adversity should be something of an object lesson.

Letters to the Editor

THE PROSPECT OF GENERAL PRACTICE

SIR,—As a young general practitioner I find myself in complete disagreement with the conclusions of your correspondent (Aug. 16). At medical school my teachers did not deride general practitioners but named certain good ones and demonstrated their letters as examples of clinical judgment and observation. Some of those whom I knew personally excited my admiration and respect as much as my hospital chiefs did, so I entered general practice biased for, rather than against, it. After 5 years in it I would not change my job, and to find out why, I asked myself the questions which your correspondent answered with such crushing negatives.

1. Have I got conditions of work which allow me to exercise my technical skill and satisfy my intellectual thirst? Yes. In a moderate-sized partnership I do have time to examine my patients. I have no less equipment in my consulting-room than the specialist has in his; but, although I do not personally carry out barium meals, blood and chemical examinations, electrocardiographs, and so on, my interest in the result of these tests is no less and my satisfaction is as great if they prove me right. And my opportunities for follow-up are considerably greater: my patients give me no option but to follow them up, whereas the specialist often depends on me for further news of them.

2. Can I provide a happy family life for my children and bring them up in conditions which will let them be moderately civilised and well educated? Yes. Although I have to work harder than most men for a decent living, I do not need to put in the hours your correspondent suggests. My wife must answer telephones and doorbells on top of her domestic duties; but since she, I, or some other responsible person must always be in the house anyway for the children this is not quite the tie it seems. When one of my partners is on duty we can go out together, and local help is as willing to come to a doctor's house as to any other. Our children, it is true, must not scream and shout immediately outside the consulting-room door; but this is no great hardship for them. And since I did not find among my school and university contemporaries that doctors' sons were less civilised than other people's I do not worry on that score.

3. Does general practice allow me to work without thought of gain? No, but what occupation does? The well-educated member of any profession would surely spend more time in the theatre and the art gallery and less at his work if he were free from that stimulus. What could be more civilised for the salaried G.P. than to drop 1000 patients and devote the time gained to reading philosophy or playing the flute? Am I blackmailed by hostile circumstances? No. Legally the patient has the whip hand; but if he is thoughtless or stupid, or makes unnecessary demands, I no more hesitate to tell him so than my father did his private patients a generation ago. I lose no more patients in this way than I gain through my rivals taking the same line. The patient may report me to the executive council, but unless he has a genuine grievance he involves me in no more than an explanatory letter.

4. If my health falters my livelihood is endangered, but no more so than in any other job. The edicts of the Ministry of Health can surely seldom conflict with anybody's principles, and its regional medical officers do not spend their time searching our records for mistakes. As for the threat of my competitor getting a seat on the regional board, this would delight me because his administrative duties would leave him less time to compete against me without in any way increasing his attraction to my patients.

I do not wish to idealise general practice. It is hard work—it has its frustrations and annoyances, and it involves too much routine paper work—but it can be spiritually and intellectually satisfying and I believe in its future. It is important that good doctors should continue to be attracted to it; and for this reason articles like your correspondent's, which give a false picture, should be answered.

Newcastle upon Tyne. ANDREW SMITH.

SIR,—I would like to support Dr. Hanratty (Aug. 23) in his reply to your anonymous correspondent. General practice has always been just what the individual practitioner wished to make of it. This, for many of us, is its charm. In many ways this is more true now than ever before. Freed from the bar of money, a doctor can follow his cases as far as he wishes.

As for the "insults, stupidity, thoughtlessness, and unnecessary demands" of his patients, it is obvious that your correspondent has never thought of himself as the family doctor who is not only an adviser but a friend. Patients do not treat their doctors thus unless goaded by the unfriendly and unwilling attitude of the doctor. In my practice unnecessary calls are extremely rare; and night calls, apart from midwifery, very rare indeed.

There will be no research in general practice as long as the conception of research is one of a technical process requiring expensive apparatus. To my mind the general practitioner's research should be careful observation of the vast quantities of clinical and social material at his disposal. He should be able to call upon the services of a department of social medicine to help him to collect and analyse the material.

Possibly your correspondent will be surprised to hear that I not only chose general practice, but I enjoy it and would choose it again. Perhaps there are dissatisfied practitioners. If there are, I suggest they cease to look for outside causes of their dissatisfaction and apply the remedy from within themselves.

York. F. CHARLOTTE NAISH.

SIR,—Your correspondent certainly "went to town." The prospect is not so melodramatic, though full of poetic justice.

We have produced a breed of academic medicos, "lily-livered" when it comes to facing clinical medicine in the great unknown—outside the hospital ward, outpatient department, or examination halls. If you want general practice you must go and get it by proving your individual intrinsic value to the individual patient. The patient that seeks a doctor out is worth twenty dished up to him by official assignment or in a clinic: the relationship, a very personal and intimate one, starts propitiously in this personal approach.

There are still many openings for the man of courage and initiative combined with ability and a vocational calling. Let him put up his plate in a large residential or populous district, or where studied report bemoans the lack of a good doctor—a complaint I hear often. He will not have to wait very long before he is established if he gives good service.

The dissatisfied patient—and there are many more of them now than when I started in practice—is waiting for a G.P. whom he can approach on an equal footing, prepared to give time and interest to his case. He does not want, and certainly will not regard, as his G.P. the pen-pushing Civil Service drudge to whom he goes for certificates which could be as easily obtained at the post office counter, and with less waiting.

When I see a few well-qualified young men—and women—with courage and a vocational urge to treat and heal the sick putting up their plates and ready to deliver the goods I shall feel happier about the future, not only of medicine, but of the young Elizabethans.

London, W.1. W. PINNINGTON JENSON.

SIR,—Your correspondent paints a grim picture; but it is the work of a blindfold artist, for he confesses that he has not done any general practice.

Your correspondent's remarks were answered specifically by Dr. Hanratty. I would only add, first, that general practice offers great scope for research,[1] particularly into old age and its problems; and, secondly, that hospitals are, in my experience, only too pleased to allow the G.P. to have direct access to laboratory and X-ray departments. If this cuts down their out-patients and prevents unnecessary admissions, so much the better.

---

[1] See Fry, J. *Brit. med. J.* Aug 2, 1952, p. 219.

Let us have criticism of general practice, but let it be first-hand. Sir, are you prepared to print an anonymous article by a G.P. on the Prospect of Academic Research?

London, W.11. L. MELVIN GREEN.

SIR,—It was with amazement that I read your correspondent's article. Not one word or thought of medicine as a vocation relieves this cry of woe. Surely he considered the attractions of other methods of earning a livelihood before he became disillusioned and entered his medical school to train as a doctor. Did he not realise that patients are ill during the night as well as during the day, and that office hours cannot be followed in medicine; or why else does he complain about the need to be available throughout the 24 hours?

A patient is a sick person—the same as any other of the writer's fellow men a day or a week ago, but now in pain or distress—*not a creature apart, full of* insults, stupidity, or wicked demands veiling his threat of legal action behind a whining plea for this and that. Now, as in the past, he is grateful for the care and attention given to him by his own doctor, and he is still the same person, "the victim of the often appalling mistakes," who appears tucked up in his hospital bed, and not a creature metamorphosed by the high technical skill of the consultant at the teaching hospital.

Let the writer analyse his training afresh. Does he wish to estimate each chemical abnormality, to have a radiograph for each râle and rhonchus, to record each extrasystole on shining paper—meanwhile what of the patients who lie in their homes while the scientifically trained doctor is cogitating over his tubes, his cardiographs, and radiographs. The patient will turn to the doctor who has learnt the art and science of diagnosis by observation and inspection, by bedside examination, and one who then can use his scientific background to call for tests from those working in laboratories.

The general practitioner has bowed to the seizure of his goodwill by the State, though he knows new and complicated problems have risen thereby—but he is still not salaried. We think that a salaried service will produce uniformity and loss of drive and ambition—abstract qualities that are difficult to formulate.

There are many outside general practice and on the threshold of medicine who do not know the anxieties and fears when one has the responsibility of a patient's life in one's hands—and the satisfied pleasure when that responsibility is discharged with credit. There are many who can only think of the team around the bed in the great teaching hospital, where the personal onus of care is not so heavily on one man, where the relatives are not watching each move and action, and where the patient's friends do not have to be met and spoken to each day.

No! General practice will still take many of the "good" doctors, and more will enter the ranks if others on the threshold stop crying when they see a little of the hardship and none of the rewards of this great vocation.

G.P.

SIR,—I read with mixed feelings of horror and indignation your correspondent's article. It is a complete travesty of the facts.

I have time, and am able, to investigate fully all patients needing it—X rays, full laboratory facilities, and hospital beds are at my disposal should I need them. I find, however, that I can do almost all medical investigation without hospital beds, reserving these for biopsies only; when a patient requires specialist treatment he usually attends the consultant with the investigations already completed.

If the practitioner is sympathetic and does a good job, prescribes for his patients what is good for them—not what they want—gives certificates where it is justifiable and refuses them otherwise (however much longer that may take) he will be respected by his patients; he will not be abused either literally or with thoughtlessness, and he will find peace and satisfaction in his work.

Surbiton, Surrey. DUNCAN MILNE.

SIR,—As a literary exercise The Prospect of General Practice would no doubt acquire high marks—but not from a general practitioner of any experience. Your correspondent has, it appears, spent his days so far in lofty academic circles. All he needs now is to spend a year or two in general practice which will be worth any amount of theorising on the subject. Research in general practice, one may remind him, will not come by sitting down and taking thought. It will have to come by patient waiting, and, as he correctly surmises, the duties of each day are sufficient in themselves.

General practice is only one division of medical practice, and those who follow it must be content to be G.P.S and nothing else. It is true that mistakes are made in general practice—some quite unforgivable—but one has only to read the daily papers to know of horrifying mistakes made in hospitals.

Your correspondent's gloomy views about bringing up his children, and about life in general practice, have no basis in fact. As one who has seen many years of it, I can safely say that general practice today is far more bearable than it was under the National Health Insurance. Patients are more considerate and are more prone to regard the doctor as a human being and not as an automaton. All the same it can be very exacting, and at times, even exhausting.

In conclusion I should like to assure your correspondent that, even though he and his like decide not to enter general practice, that particular division of medical labour will continue to carry out, satisfactorily in the main, the bulk of the medical work of the country as it always has done; and, taking it all in all, that work will compare favourably with anything that may be done in hospitals.

Brighton. G. L. DAVIES.

SIR,—As a final-year student, I find it alarming to have my intended branch of the profession denigrated by such remarks as "low professional standard and lack of opportunity for good work."

I have been privileged to accompany a G.P. on his rounds and attend his surgeries, and I was impressed by the modern techniques and remedies employed and by the care with which they were used. It was also interesting to observe the complete mutual confidence between the partners in the practice, which resulted in not ungenerous periods of leisure free from worry.

I fear, however, that your correspondent's pessimistic article will disuade some of those about to qualify from entering general practice.

Middlesex Hospital Medical School,
London, W.1. J. D. WIGDAHL.

SIR,—Through his specialist glasses your correspondent sees too darkly the prospect of general practice. There is no doubt that the emphasis since the introduction of the National Health Service on the development of the hospital and specialist services, and the almost complete neglect of the general-practitioner services, have reacted to the disadvantage of general practice.

Let us remember, however, that one of the most important reasons for the National Health Service Act, was the tottering state of our domiciliary services, which in many ways were showing signs of severe strain. When after July, 1948, great numbers of people who previously could not afford a doctor of their own very naturally took advantage of their new-found opportunity, the situation in many areas became almost chaotic. Far from seeing the new situation as a revelation of the inadequacy of pre-service conditions, those unsympathetically inclined put the blame on the new service.

Even as at present constituted, the National Health Service presents an opportunity for raising general practice to the level already reached by the hospital and specialist services. This lies, I believe, in the development of group practice from health centres, for which the Act makes statutory provision. Unfortunately, just as Lord Dawson's original recommendation for health centres, put forward in 1920, was pigeon-holed because of economic pressure, so today health centres, although described by the Minister who introduced the Act as the keystone of our domiciliary service, have again, ostensibly for the same reason, been held up except for a few already being built. These few are very substantial buildings; but it does not seem unreasonable to suggest, with our lack of experience of how health centres can best function, that more temporary prefabricated structures, designed for adaptation to changing needs, might have better served the purpose of what is really a pilot study.

Group practice in health centres involves the coöperation of doctors, nurses, social workers, technicians, and other ancillary staff. This calls for coördinated action by the regional hospital board, local health authority, and local executive council, which are the administrative bodies concerned. At present no statutory body coördinates the activities of these three; and it seems very necessary in the interests of an efficient domiciliary service that there should be set up some such coördinating committee, called perhaps an area health service council.

While in many respects the Working Party's report is disappointing, its recommendations will go some way to redress the balance between the specialist and general-practitioner services. It is much to be regretted that its contribution to the establishment of group practice is so lukewarm.

For many reasons general practice today is far from being as good as we were promised, and as it could be under the terms of the National Health Service Act. Nevertheless, after 28 years' experience in a mostly industrial practice, I can confidently assert that the high standards to which your correspondent quite rightly aspires are more nearly attainable today than before the introduction of the service four years ago.

Edinburgh. S. LIPETZ.

SIR,—The time has really come when correspondents to the medical journals on matters concerning the National Health Service should appreciate the true facts. The letters which appear from week to week, if read by any uninformed person, must cause serious damage to the medical profession. The following statements are often found:

That doctors are inundated with clerical work and are thus unable to give proper attention to their patients.

Most of us have less clerical work than we had in the days of private practice. Sending out bills and recording and collecting fees was an onerous task that no longer exists. The keeping of records is no more than any doctor had to do for all his patients in the old days. Prescriptions have always had to be written, even for private patients.

That we have lost the freedom to practise that we had in the days before the National Health Service.

We are now at liberty—and it is a great advantage—to call on patients as often as they need without any consideration of whether they can afford it or not. Patients can be expected to visit us, rather than that we should be expected to visit them at their own convenience.

That we have lost the freedom of prescribing what we consider patients need.

Never were we able, in the past, to prescribe drugs regardless of their cost. In the days of private practice any doctor should have borne in mind the cost to the patient of expensive drugs. Any good doctor would have considered whether the high cost of a certain drug was justified by its clinical action. The less conscientious doctor considered that what the chemist received he lost.

That we have lost the freedom to sell the goodwill of our practices.

Most of us borrowed the money to buy a practice in the days before the war, and it took us very many years to repay the cost of purchase. Now, with income-tax at a high rate, no young man can ever expect to repay the purchase price of a practice. The freedom now bestowed on the incoming partner and the intaking partner must be felt personally to be realised.

The financial side of medical practice under inflation should also be realised. Because the pound is worth only half what it was before the war, the fees in private practice should be increased to twice what they were then. The experience of most general practitioners must be that, far from being able to double their fees, they find that most patients feel that they need a decrease if they are to remain as private patients.

Petworth, Sussex. W. A. BALL.

LEAD PAINT: A HAZARD TO CHILDREN

SIR,—I had intended on my return to this country to inquire about the known incidence of lead poisoning in children and to ask my clinical friends to bear in mind that it might be occurring. I was, therefore, most interested in the article on this subject by Dr. Millichap and his colleagues in your issue of Aug. 23.

The city of Baltimore, Maryland, has a population of 950,000. During the period 1931–51 there have been in that city 293 cases of lead poisoning in children, of which 83 have been fatal. The age-distribution of the 293 cases, with deaths of the 83 in parentheses, was: under 1 year, 19 (8); 2 years, 167 (51); 3 years, 67 (15); 4 years, 21 (3); 5 years, 11 (2); over 5 years, 8 (4).

Cases are still occurring, despite the efforts of the health department to warn parents not to allow their children to chew painted toys or paintwork on window-sills. There were 34 cases in 1949, 31 in 1950, and 20 in the first six months of 1951. The peak period is July and August.

A recent city ordinance has prohibited the use, for indoor painting, of paint unless it is free from any lead pigment; and a free service for the examination of blood for punctate basophilia is provided by the city health department.

ALLEN DALEY
Recently Associate Health Officer,
Baltimore, Maryland.
London, W.14.

SIR,—Two children seen at this hospital in the past three months emphasise the plea made by Dr. Millichap and his colleagues for the recognition of the danger to young children in lead-containing paints. These cases also emphasise the need to consider the diagnosis of lead poisoning in children with vague cerebral symptoms, such as irritability and vomiting, and abnormal cerebrospinal fluid.

Both patients, aged 3 years and 16 months, presented with irritability and vomiting, and a diagnosis of tuberculous meningitis was considered. Pallor was, however, marked in the second child, and, taken in conjunction with the cerebrospinal fluid (C.S.F.) findings, suggested the diagnosis before more specific evidence was obtained. In both, the C.S.F. findings were typical of lead encephalopathy; lead lines were present in the bones; the punctate-basophil count was high (Lane's technique); and there was a high urinary-lead excretion. The first child is of special interest; for she was found to have a megaloblastic bone-marrow, and her case will be reported more fully in due course.

The source of lead in the first case is not yet definitely established, but the second child had ingested lead from the old and crumbling paintwork of an outside balcony. The lead content of the paint was 54% (calculated as the metal).

There is clearly a need for more safeguards against this danger than exist at present.

Whittington Hospital,
London, N.19.
M. B. MORRIS.

ACTION OF ANTIBIOTICS

SIR,—I consider it dangerous to let your interesting leading article of Aug. 23 pass without comment, especially in so far as penicillin action is concerned.

That penicillin affects the assimilation of glutamic acid is beyond doubt, but it is equally beyond doubt that death of the cell does not come about because it has been deprived of the vital preformed glutamic acid. Many penicillin-sensitive staphylococci will grow without added glutamic acid and a *Bacillus subtilis* has been described which is extremely sensitive to penicillin, even when growing on a medium composed of inorganic salts and glucose only. Thus, we can have both penicillin-sensitive and penicillin-resistant organisms which are nutritionally independent of preformed glutamic acid or of any other amino acid. Dr. E. F. Gale, who has done such excellent work on this subject, has wisely avoided jumping to the easy conclusions which you expound. In spite of the tremendous amount of work done in the last few years on the mode of action of antibiotics, we are far from understanding how any of them works.

DERRICK ROWLEY.

ATTENDANCE AT BOXING CONTESTS

SIR,—We are anxious to obtain the voluntary services of medical men to attend amateur boxing shows in London and the suburbs during the coming autumn and winter.

The shows usually take place in the evening, and the duties consist in examining the contestants (total time $^1/_2$–$^3/_4$ hour) and being available or on call for any serious injuries, which are usually very few. The only reward we can offer is a good boxing show and a convivial evening.

Medical officers will have the satisfaction of knowing that they are assisting to foster a high physical and moral standard in the health of the nation's youth.

Will doctors who are interested please write to me?

London Amateur Boxing Association,
69, Victoria Street, London, S.W.1.
J. L. BLONSTEIN
Hon. Medical Officer.

BLOOD-PRESSURE ESTIMATIONS IN CHILDREN

SIR,—Your explanation (Aug. 16) that you were referring to research conditions in your leading article on the treatment of bacterial meningitis disposes at once of two of my objections to your proposed scheme of blood-pressure estimations—namely, that child manometer cuffs are not generally available, and that the suggested procedure would prove appallingly time-consuming. But not, I think, of my third, and perhaps most important, objection—that in most cases even when a reading has been obtained its value is doubtful.

The Waterhouse-Friderichsen syndrome occurs predominantly in young children, often very young children. Though desperately ill they are not, unless in the terminal stages, inert; on the contrary they are restless and resistive. They struggle against the manometer cuff and have to be firmly held. Of what value are readings obtained under such restraint? And are we justified in provoking these patients to expend their diminishing reserves of strength for the sake of such equivocal findings? By all means let us have as many accurate blood-pressure estimations as we can in coöperative patients; I agree that they afford valuable confirmatory evidence in diagnosis. But diagnosis is not so difficult as suggested, and, with respect, has seldom to be made from other very severe forms of ordinary meningitis, for in fact there is little similarity between the two conditions. The crucial feature of the Waterhouse-Friderichsen syndrome is that signs of meningitis are either extremely slight or, more usually, absent, and the conditions usually suggested to the clinician are malignant purpura or pneumonia.

Perhaps I can make my position clearer if I say that in my view any patient who presents with collapse and a purpuric or ecchymotic (*not* petechial) rash, particularly if there is livid cyanosis and perhaps polypnœa, should have a lumbar puncture. If this reveals an opalescent or turbid fluid under increased pressure, cortisone and sulphonamides should be given without delay; for this is one of the most acute emergencies in medicine—one has seen a patient die within 12 hours of taking ill. The amount of cortisone required is relatively negligible. I agree that its value in this syndrome should be most carefully assessed; but I submit that this has already been shown to be considerable; and if we are to wait until correct blood-pressure estimations have been made, then I submit, Sir, that many lives will be lost that might otherwise be saved.

CAROB FLOUR IN FUNCTIONAL VOMITING OF INFANTS

SIR,—Most babies who frequently vomit or regurgitate their food are just mild "posseters," but a few belong to the more serious and even alarming class of "habitual vomiters." These babies may reject their food any time within an hour of feeding. The trouble may start very soon after birth in either breast- or bottle-fed children. When an organic cause has been excluded, the diagnosis of "habitual vomiting" may reasonably be made. This is a functional disturbance of ingestion which includes cardio-œsophageal relaxation.[1] The problem of getting the baby to retain its food must then be tackled.

Most infants come to no harm from occasional or even quite regular vomiting, but the baby whose weight stays the same or actually falls is in danger, and undernourishment may lead to dehydration and atrophy. And in spite of this the infant is hungry, alert, and avid for food which it cannot hold.

The usual treatment is to thicken the food by adding, say, wheat flour or arrowroot to the milk formula or to the expressed breast-milk, thereby increasing the viscosity of the milk and helping to keep it in the stomach. Phenobarbitone may also be given before each feed. These measures usually work in the simpler cases. Fine-oatmeal gruel and pureed potato made with milk are sometimes used, or the consistence of the feed may be suitably altered by using powdered or condensed milks, extra fluid being given as water between feeds. Whatever method is used there is an important disadvantage—the formula is poorly balanced for the infant's nutritional needs, and growth may be affected.

It was with much relief that I heard of Professor Lelong's work in Paris on this problem. All degrees of persistent functional emesis in infants were treated with milk thickened by the addition of carob flour, a powder extracted from the seed of the Levantine carob tree. Information about this legume, *Ceratonia siliqua* (Linne), is given by Glanzmann.[2] This flour was prepared for Professor Lelong's trials by the Nestlé Company of Switzerland, and has proved indispensable. Its virtues are that it has no flavour, it thickens the milk without lessening its digestibility or changing its nutritive value, and it is completely inert and neutral. But it does alter the consistence of the feed so that it is rare for even a severe case not to respond satisfactorily.

---

[1] Neuhauser, E. B. D., Berenberg, W. *Radiology*, 1947, 48, 480.

[2] Glanzmann, E. Einführung in die Kinderheilkunde. Vienna, 1949; p. 220.

0·5–2% (usually 1%) of the powder is added to each feed—i.e., one measure to 100 ml. (3 ounces) of cold breast, ordinary, or modified milk. Any sugar and water required is added to this mixture, and the whole is brought to the boil. When powdered or condensed (evaporated) milk is used, the powder is mixed with the necessary water, and the mixture brought to the boil for a moment before the milk is added with vigorous beating.

Carob flour is available on the Continent and is widely used in Switzerland, France, and Belgium. In this country the powder, which is marketed abroad under the trade name of 'Nestargel,' has received only one mention as far as I know; Evans and Mac Keith[3] say: "The addition of ½–1% of 'Poudre Épaississante Nestlé' Nestargel to the feed makes it so adhesive that the child cannot vomit it, but this preparation is as yet not generally obtainable."

The import of carob flour for sale in the United Kingdom is forbidden, and the flour which I have myself used was kindly supplied by the Nestlé Company. I have only been able to try it so far in nine cases, but all these have been severe enough to resist all routine measures. All nine babies were cured or remarkably improved in a very short time, all within two weeks and the majority within a week. The mothers were given the powder with instructions on its use, and they had no difficulty in preparing the feeds.

I have no doubt of the efficacy of carob flour in this condition. Its value deserves to be widely known, and the flour should be readily obtainable. I would go so far as to say that if there is no improvement after its use, the diagnosis of the cause of vomiting must be suspect. Before others can share my enthusiasm, the ban on the sale of carob flour in Britain must be lifted.

Dr. Helen Morley kindly provided me with several of the patients in my small series.

NURSES IN THE MAKING

SIR,—Mr. Hodkinson's letter[4] has been followed by a leading article in your issue of Aug. 9.

My experience of a cadet scheme in this mental-deficiency hospital appears to run parallel to that of Mr. Hodkinson, even to the intention not to publicise it until more experience had been gained. The scheme has now been running for nearly 3 years, and results hitherto have been wholly satisfactory.

Two whole days a week are spent in school on "further education" with a teacher provided by the local authority. Three half-days a week are devoted, under the supervision of our nurse-training school, to subjects which will lead up to the preliminary State examination; and three half-days are spent in the various departments of the hospital. These young people are at no time regarded as nurses, and their status in the hospital is that of a student; association with all but the youngest patients is minimal, and regulations regarding the employment of young persons are strictly adhered to, although in view of the student status of the cadets these regulations rarely apply.

Mr. Hodkinson lists five advantages and five essential features. I have just looked up one of my earlier reports on our cadet scheme, and find that I came to the same conclusions, in almost the same order and the same words. If I had to select one outstanding element in the success of any cadet scheme, I would say that this is the "student" as opposed to the "employee" status of the cadet; and I would add that in this hospital we accept the "career" element in nursing, as opposed to the "vocation." All young people on application are medically examined and educationally and psychologically tested; and we believe that the young men or women who tell us that they wish to take up nursing because the career seems interesting, the money is good, and they wish some day to be a chief male nurse or matron, are better candidates than those who claim they have a call to do nursing. On inquiry this too often is found to mean that they have a call for nothing and that they are just drifting into nursing and will thus probably drift out again.

The cadet scheme in this hospital is practically our only source of student-nurse recruitment; it has saved the nurse-training school from extinction and the hospital from the closure of beds.

The raising of the minimum age for student nurses to 18 years is a blow to nurse recruitment, but not, I think, too serious a blow; it will dam but will not choke the stream.

Your statement that "there are good arguments for the view that whatever a girl does between leaving school and starting her nursing training, at least she should keep clear of hospitals" is a denial of the fact that some hospitals can lay themselves out to ensure that everything that can be done is done to provide for the proper mental, physical, and emotional maturation of the young male or female nursing cadet.

I believe that properly run cadet schemes, run on "further education" lines, are the answer to the nursing shortage. I also believe that badly run schemes are likely to cause much harm to nursing recruitment.

Prudhoe-on-Tyne, Northumberland.
GEORGE MCCOULL.

INCISION FOR APPENDICECTOMY

SIR,—I was very interested in Mr. Young's account (Aug. 9) of his method of extending Battle's incision where pelvic or other disorders are unexpectedly encountered.

I have used in about a hundred cases a method which, for want of a better name, I call the "transverse retro-rectal approach," and which also may be extended if necessary.

An incision is made in the plane between the anterior superior spines of the ilium. Starting in the midline and extending to the right over the right rectus abdominis muscle, it may be made in the natural crease which often lies at this level. The rectus sheath is opened in the same direction as the skin incision; the rectus muscle is freed from its sheath posteriorly by stripping it with the index fingers, and the muscle is retracted medially. The posterior lamella of the rectus sheath with the closely adherent transversalis fascia and peritoneum is picked up above the level of the linea semicircularis and opened transversely: care must be taken not to include the gut, which is closely applied to the peritoneum here. The inferior epigastric artery, which has just entered the sheath across the linea semicircularis, is medial; it is usually adherent to the rectus muscle and is retracted with it.

If a pelvic or abdominal condition requiring a more extensive exposure be encountered the approach may be converted into a Pfannenstiel by extending the skin incision transversely to the left over the left rectus muscle, opening the left rectus sheath in the line of the skin incision, separating and retracting laterally the recti muscles, and extending the previous opening behind the right rectus transversely behind the left rectus. It is, of course, possible to extend the incision to the right by cutting through or separating the oblique and transversus muscles as in Weir's approach.

The advantages of the approach are that it is adequate, and the pelvic organs can be easily examined; and the incision can be extended without damage to nerves and, possibly, consequent hernia. Wound healing is earlier; sutures may be removed on the fifth day. The scar is thin, strong, and almost invisible. Keloid formation is rare—possibly because the incision lies in the natural

skin-tension lines of Langer. The scar does not tend to stretch, and as it is transverse and often in the crease line it is cosmetically satisfactory.

HYPOGLYCÆMIA IN ROAD USERS

SIR,—Motor accidents have very rarely occurred because of hypoglycæmia in diabetics who are taking insulin. This condition may arise from several causes, such as omitting to eat the necessary carbohydrate at the usual time—i.e., at breakfast, in the middle of the morning, at the midday meal, at tea-time, or at the evening meal. If the carbohydrate is either omitted or delayed, a severe reaction may occur owing to unopposed overaction of the insulin. A hypoglycæmic attack may also be produced by taking unusual exercise shortly before the car is driven, or as a result of changing a wheel.

The medical advisory committee of the Diabetic Association therefore asks all doctors looking after diabetics taking insulin and driving motor-cars, or riding motor or pedal cycles, to make certain that their patients understand the possible causes of hypoglycæmic attacks and how they can be prevented by regular intake of carbohydrate at the usual meals, which should be taken punctually. Some extra carbohydrate should be eaten both before and after any unusual exercise. A supply of biscuits or 12 lumps of sugar or glucose should always be carried in the car or cycle in case a meal is unavoidably delayed, or unexpected exercise is necessary.

The committee especially hopes that, if a doctor knows that a patient sometimes does not recognise the symptoms of hypoglycæmia, he will advise his patient not to apply for a driving licence.

FLUORINE INTAKE IN BRITAIN

SIR,—The decrease in the incidence and spread of dental caries in certain townships in the United States, resulting from the fluoridation of communal drinking-waters, has led to the suggestion that fluorine should be added to British public water-supplies at a concentration of one part per million which, together with the ingestion of fluorine in ordinary food, would put the total daily fluorine intake at about 2·20 mg.[1 2] Subsequently a basic ethical objection to such compusory mass medication was made on behalf of the League of British Housewives.[3]

Considerations of the real differences in nutrition and distribution of population between different countries appear to have been neglected by those responsible for the suggested fluoridation of water-supplies. Small amounts of fluorine occur naturally in many sources of British drinking-waters; but fluorine-containing ores, fluxes, and coals are now used industrially in this country in large quantities. Fluorine compounds are toxic when inspired or ingested; and, since they may be encountered in various ways in industrial processes, they present a definite hazard to the health of man and animals. Animal fluorosis is being increasingly noted by British farmers and veterinary officers, especially in the neighbourhood of iron and steel works and of coal-consuming electric power stations.

Animals can be moved from contaminated pasture, but human beings remain in a polluted atmosphere. The etching of window glass by hydrofluoric acid—an easily recognised sign of atmospheric pollution—is now seen in industrial homes; and in these contaminated regions, examination of the teeth of children and estimation of urinary fluorine in adults gives evidence of the absorption of fluorine in excess of that known to come from the local drinking-water.

In a healthy man a fluorine intake of up to 5 mg. daily can be eliminated, but above this level there is retention of fluorine in the body with cumulative effects in bone.[4] A recent investigation [5] has described the effects of chronic fluorosis on kidney structure and function in rats, with a view to demonstrating the existence of a fluorine hazard before such severe intoxication has resulted as to cause obvious skeletal lesions; the histological examination indicated that in the kidneys there was vascular, glomerular, and more obviously tubular, degeneration leading to interstitial fibrosis.

We do not know how high the actual intake of fluorine is at present in the various industrial regions of this country, and, until further inquiry is undertaken with regard to the fluorine hazards to which different neighbourhoods are now exposed, it seems most undesirable that fluorine should be added to public water-supplies in Britain.

University of Oxford.

DAGMAR WILSON.

BONE REGENERATION

SIR,—Following your survey of this subject (Aug. 23) I should like to refer to recent work on bone grafts carried out in this department by Mr. John Hutchison.[6]

Bone autografts and homografts were implanted into bone, muscle, and the anterior chamber of the eye of rabbits, and their histological progress followed and compared from 10 to 180 days. Hutchison's findings are in many respects contrary to those recorded by Barth [7] and Reynolds and Oliver [8] to which you referred. Even at an early stage (10–21 days) there is a striking difference in the histological appearance of autografts and homografts. In the bone autograft, while the osteocytes, more particularly the centrally situated cells, die, the soft-tissue elements of the graft—periosteum, lining of Haversian canals, and endosteum—show active cellular proliferation and are responsible for the subsequent cellular repopulation of the graft which is complete after 40 days. The bony matrix retains its staining affinity, and by 42 days the picture is that of active living bone with no evidence of any dead bone, as implied in your article.

The autograft at 42 days therefore represents bone formed by the original cell elements of the graft and may well include much of the original bony matrix of the graft. As these cells constitute the essential living part of bone and are largely responsible for the new bone formation it is evident that the autografts survive. The period required for complete recovery varies according to the type of graft, and is naturally longer in dense cortical grafts. By contrast, sections of the bone homografts from 10 days onwards show typical dead bone with empty lacunæ and faintly stained opaque matrix —the classical sequestrum. There is, with an odd exception, no absorption of the dead homografts, which can be recovered 180 days after implantation.

Hutchison's findings correspond to those recently recorded in an experimental study by Ray et al.[9] Ham [10] has also noted the osteogenic activity of the surviving cells of bone autografts.

Both heterotopic bone autografts and homografts induced active osteogenesis by the connective tissue of the host from 10 to 42 days, which then ceased. In the case of homografts this new bone formed by the host tissue died after 42 days and was added to the graft

10. Ham, A. W. *Ibid*, p. 701.

sequestrum. Unlike Urist and McLean,[11] Hutchison found little evidence of host osteogenesis in intra-ocular transplants of bone autografts or homografts, and he concluded that this was due to the absence of marked tissue reaction. Ham is of the opinion that osteogenesis following implantation of bone grafts into muscle is entirely due to the surviving cells of the graft, and not to metaplasia of host connective-tissue cells. While this is not the generally accepted view, it would explain the death of the new bone formed around the implanted bone homograft.

Thus the behaviour of bone grafts in a general way resembles that of other tissue grafts—autografts survive and homografts die (except, of course, cornea and cartilage). The more critical initial test period before the bone autograft "takes" is to be expected because of the difficulty in vascularisation.

FEEDING DISORDERS IN INFANTS

SIR,—In his comments (Aug. 16) on Sister Morrison's letter, Dr. Wood introduces a new theme—the advice given in the lay press—possibly because he happens to know that this is the medium for Sister Morrison's work.

She would not wish to reply about the success of her own work, but I think it should be known that mothers constantly write back that after they have followed her advice their babies are contented and progressing well. So far from being "baffled," the mothers are given a sense of reassurance and confidence.

Why should it be doubted that writers for the lay press have just as keen a sense of responsibility—and just the same range of opinion—as other members of their professions? And seeing their advice in type gives them the incentive, and the opportunity, to make it as clear as possible.

London, E.C.4. MADELEINE POTTENGER.

BOOKS ON HOSPITALS

SIR,—I beg leave to supplement your correspondent's contribution (Aug. 23) on this subject with the titles of a few excellent publications he has omitted.

The functional evolution and the geographical distribution of early English hospitals is well described in *The Medieval Hospitals of England* by Mary Clay (1909), and in *Houses of Pity* by J. E. Hobson (1926). Two hundred years' history of Dublin's Rotunda Hospital has been recently recorded in two books which were reviewed in your columns.[12] In the same week the *British Medical Journal* published an interesting brief account[13] of the seven centuries' history of Europe's first mental hospital—the Bethlem Royal.

There are also two small books well worth reading which deal with the history and management of most of London's non-teaching hospitals. *The Metropolitan Asylums Board and its Work 1867–1930*, written by Sir Allan Powell, was published by the Board in 1930 and describes the vicissitudes of its 44 fever, mental, tuberculosis, children's, and special hospitals with 24,000 beds. *The L.C.C. Hospitals—a Retrospect* was published by the London County Council in 1949, and carries forward the history of 98 of London's "poor-law" and municipal hospitals with 72,000 beds from 1930 to 1948.

The Ministry of Health, which now controls most of the hospitals in England and Wales, has an unrivalled opportunity, which it should not miss, to produce the most up-to-date book on the hospital history of this country.

London, S.E.1. WILLIAM HARTSTON.

TREATMENT OF PULMONARY TUBERCULOSIS

SIR,—The symposium in your issue of Aug. 23 makes it clear that the treatment of pulmonary tuberculosis at Clare Hall Hospital is based on very sound principles.

There may be disagreement, however, with one of Dr. Macdonald's observations on the use of artificial pneumothorax. He says: "We hesitate to do a pneumothorax . . . of course . . . if there is too little disease." This hesitation would appear to originate in a wish to avoid serious complications, or possibly in a suspicion that the procedure might be unnecessary. But empyema, fistula, and inexpansible lung usually result from the use of pneumothorax treatment in unsuitable cases.[1] When the disease is minimal ("too little"), such complications need not ordinarily be expected. The observed prognosis of minimal pulmonary tuberculosis is not good, between 20% and 80% of cases showing progression during the first 2–3 years after diagnosis.[2–8] Early collapse therapy can improve the prognosis.[9–11] Therefore, neither of the presumed objections to the use of pneumothorax in minimal disease seems valid.

Many patients with minimal tuberculosis are now referred to the chest clinics from mass-radiography units. Adolescents and young adults form the majority of such cases. Progression of disease can be expected in a high percentage of these young people. Their supervision commonly consists in the inspection of serial radiographs taken at intervals of 3 to 6 months. But diffuse bronchogenic spread and cavitation during the intervening months is seen all too often. The advantage of early diagnosis is then lost. Any minimal disease which has shown the slightest tendency to progress whilst closely observed is probably one of "the positive criteria for inducing a pneumothorax" which your leading article seeks.

Poole Sanatorium, Nunthorpe,
nr. Middlesbrough. J. P. ANDERSON.

SIR,—The excellent article by Dr. Simmonds and his colleagues interested and instructed me. I was, however, pained to note the reference to "resection-minded Liverpool." I thought this bogy had been well and truly laid by Coope, but apparently it has to be done again.

There are in Liverpool a number of thoracic surgeons operating at various hospitals in coöperation with chest physicians. The number of different views on tuberculosis and its treatment is probably equal to the number of surgeons or the number of institutions concerned, whichever is the greater. F. R. Edwards and his associates, working at Aintree Hospital, have pushed the indications for resection much further than most people; but, as far as I am aware, they have never claimed that this is anything but a large-scale experiment. Other thoracic surgeons in Liverpool, in common with those in the rest of the country, will await the analysis of their cases and the 5-year follow-up figures with considerable interest, and possibly radical consequences to their future policy in treating pulmonary tuberculosis. Meanwhile, Liverpool remains a geographical area where all forms of treatment for pulmonary tuberculosis are practised, and each case is considered on its merits and the form of treatment is advised that is most likely to ensure success in the particular circumstances.

I myself find it increasingly embarrassing to have to explain to visitors and colleagues that I meet that I am in no immediate danger of forgetting how to do a thoracoplasty or an adhesion division. A general surgeon accused of being "cholecystectomy-minded" would rightly take this as a reflection on his professional judgment. The suggestion of being "anything-minded" implies that prejudice or obsession has taken the place of scientific judgment. May I please put it on record that this is not the case in Liverpool.

Liverpool. LESLIE J. TEMPLE.

MEGALOBLASTIC ANÆMIA OF PREGNANCY

SIR,—In your issue of Aug. 2 Dr. Israëls and Dr. Da Cunha emphasise the importance of early diagnosis in megaloblastic anæmia of pregnancy, as this disease is not at all rare and can be adequately treated. They state that folic acid remains the treatment of choice, because vitamin B_{12} has been found ineffective against this condition in temperate climates.

We have previously described[1] a case of megaloblastic anæmia in the puerperium reacting to vitamin B_{12}. In this case analysis of the gastric juice showed the presence of free HCl. This excluded the possibility of addisonian pernicious anæmia. Determination of the fat content of the fæces (total fat 50% of the dry weight) pointed to non-tropical sprue. We came to the conclusion that megaloblastic anæmia in pregnancy in the temperate zone may be classified as: (1) addisonian pernicious anæmia, (2) non-tropical sprue, and (3) true megaloblastic anæmia of pregnancy or puerperium.

Since then we have seen a patient of 23, primigravida. She was examined in November, 1950. Her hæmoglobin was then 12·5 g. per 100 ml. In April, 1951, she was admitted to hospital because of severe anæmia, which progressed while she was treated with iron.

The patient was 8 months pregnant. She complained of dyspnœa on exertion, headache, and œdema. She suffered from vomiting, which had improved during the last 2 or 3 weeks. Examination showed a systolic murmur. Liver and spleen were not palpable. The tongue was normal. No signs of polyneuritis or involvement of the central nervous system.

Investigations.—Hb 5·4 g. per 100 ml.; red blood-cells 1,200,000 per c.mm.; white blood-cells 10,000 per c.mm.; smear of peripheral blood showed 14 nucleated red cells (including some megaloblasts) per 100 white cells. Bone-marrow: hyperplastic, megaloblastic.

Fractional gastric analysis (free and total acidity in ml. of 0·1 *N* HCl per 100 ml.): (1) 0/27, (2) 0/5, (3) 0/7, (4) 0/12; after histamine (5) 6/6, (6) 14/30, (7) 28/45, (8) 34/48.

Serum-iron 370 µg. per 100 ml.; blood-bilirubin 0·6 mg. per 100 ml.

Fæces over a 3-day period on a Schmidt's diet: total weight 110 g.; dry weight 30·5% of total weight; total fat 29% of the dry weight.

Glucose-tolerance curve: fasting, 79 mg. per 100 ml., 30 min. 174 mg., 60 min. 149 mg., 90 min. 73 mg., 120 min. 65 mg., 150 min. 74 mg.

Treatment.—She was given 400 ml. of blood, which raised her Hb to 6·2 g. per 100 ml., her red-cell count to 1,500,000 per c.mm., and the hæmatocrit volume to 22·1%. Treatment with vitamin B_{12} was started on April 18; 15 µg. daily was given by injection for three days. On the third day she felt better, and the subjective improvement continued. It was accompanied by a reticulocyte crisis of 17·3% on the ninth day. On May 2 her Hb was 9·07 g. per 100 ml., red cells 2,180,000, and hæmatocrit volume 30%. Vitamin B_{12} was again given (15 µg. every other day) until May 13, when she was delivered of a healthy child.

Blood examination on Jan. 18, 1952, showed Hb 12·8 g. per 100 ml., and red cells 4,710,000 per c.mm.

In this case the normal fat content of the fæces and the normal glucose-tolerance curve excluded the possibility of non-tropical sprue, while the presence of free HCl after histamine is strongly against the diagnosis of addisonian pernicious anæmia.

At the University of Utrecht medical clinic Verloop[2] observed the effectiveness of vitamin B_{12} in similar patients. In the Netherlands at least, there are two groups of megaloblastic anæmia of pregnancy: the first is caused by a deficiency of vitamin B_{12}; and the second by a lack of folic acid. This differentiation is, of course, of practical importance because of the danger of neurological lesions in patients with vitamin-B_{12} deficiency who are given folic acid.

University of Groningen,
Holland. H. O. NIEWEG.

ACHALASIA *v.* CARDIOSPASM

SIR,—Hurst is dead: otherwise he would have replied to your peripatetic correspondent's attack (Aug. 16). Hurst gave up many of the concepts and therapies mentioned long before his death. "The absent acid-barrier in pernicious anæmia" was forgotten in 1928, although I well remember in 1930 Castle, who attended one of Hurst's combined rounds, saying with obvious sincerity that if Hurst had not emphasised the absence of acid and published his supposedly cured case of Addisonian anæmia, he (Castle) would never have thought of doing his experiment of predigesting a steak in a healthy stomach and transferring it to a patient with Addisonian anæmia.

Though Hurst gave up his views about catarrhal jaundice, somewhat obstinately, he never gave up the concept of achalasia. When I do a rectal examination in a patient, if he has a fistula, a fissure, or a thrombosed pile, the sphincter sometimes goes into spasm and this I call anal spasm. In people with a healthy lower gut, the finger usually slips in easily—i.e., there is complete "chalasia." Hurst constantly pointed out that when the mercury tube (I cannot remember his miscalling it a "bougie") passed into the stomach as the sphincter relaxed, the tube was not gripped as it would be in cardiospasm. It was this observation which made him ask Sir Cooper Perry "for a single word to express 'absence of relaxation.'"

This observation I confirmed this morning when I visited a patient who in the past twenty years has passed her tube over 3000 times. This woman of 53 kindly passed her tube while I waited in the next room, and I was able forthwith to show that there was no gripping, or, as she said: "When the tube passes the obstruction, which is rather difficult, there is no difficulty in withdrawing it." She, however, usually keeps it down for five minutes, and she has discovered that this suffices for two to three days of easy swallowing. She has also discovered that it helps to have had a light meal.

Your peripatetic correspondent says that Douthwaite congratulates Avery Jones on excluding "the inept word from his new book." But Avery Jones has not done so. Two of his authors, both surgeons, write thus:

Ronald Belsey (p. 156) says in the differential diagnosis of hiatus hernia from "Achalasia of the cardia. Dilatation of the œsophagus is rare in hiatus hernia, even with stenosis and usual in achalasia. The symptoms are different and the response to octyl nitrite is diagnostic of achalasia"; and Geoffrey Wooller (pp. 179–199) gives achalasia as a synonym for cardiospasm but uses the word cardiospasm "in the belief that spasm of the cardia exists in the majority of patients." although he admits: "The cause of cardiospasm is unknown. Psychogenic trauma is an important factor in initiating its onset."

I am grateful to your peripatetic correspondent for making me do a little research, and rather than try to decry Hurst's work and his disciples as he does I would like to suggest that we get more information on two unsettled points.

Firstly, several people doubt Geoffrey Rake's work,[3] confirmed by E. A. Gallinaro,[4] that achalasia is caused by degeneration of Auerbach's plexus and think this is the effect rather than the cause. Surely it is possible to examine Auerbach's plexus in patients dying from other forms of prolonged obstruction to settle this point, which has been in doubt for twenty-five years.

---

[1] Nieweg, H. O., van Buchem, F. S. P., Stenfert Kroese, W. F. *Acta med. scand.* 1952, 142, 45.

[2] Verloop, M. C. Personal communication.

[3] *Guy's Hosp. Rep.* 1926, 76, 145; *Ibid*, 1927, 77, 141.

[4] *Rass. Neurol. veg.* 1947, 4, 464.

Secondly, believing as I do that achalasia is curable by Hurst's mercury tube, the passage of which I admit is unpleasant to many people and well-nigh impossible for children, can we get some idea how often it must be passed ? Psychology plays its part, and I remember how forcefully that was impressed on me in 1924 when as a ward clerk I sat at John Ryle's feet.

> An outpatient, a boy of some eighteen years, on being asked how his achalasia was, said he was much better, had gained in weight, could swallow well, &c. Ryle, not realising that the boy had not finished, pointed out to us how Dr. Hurst had invented this tube and what great advantage the boy had received. Thereupon the boy said he had really come up to say that he had not passed the tube for some weeks when, at a religious meeting, he had received the laying-on of hands. John Ryle immediately said that was the type of discipline so good for us.

Unfortunately I cannot tell the end of the story, but G. Wooller in Avery Jones's book *Modern Trends in Gastroenterology* records instances of "cardiospasm" occurring after psychological trauma, and I am sure there are other "cures" such as the one recorded above. Until we know this we cannot really judge the value of surgical treatment ; we should also know more about the asymptomatic patients—one of whom I know, besides being the headmaster of a public school, is also a distinguished athlete. I feel that Hurst if he were alive would be the standard-bearer of surgeons who operate successfully on this condition ; but he lived in the age of "cardioplasty, œsophagoplasty and œsophagogastrostomy" which, as Wooller says, "are killing operations" ; and even though Hurst persuaded surgeons to operate, they approached the cardia abdominally, and so had no real successes.

If I have written in a partisan manner it is because, as John Ryle said in the introduction to Hurst's autobiography : "To know Hurst and his enthusiasms, his generosity, his courage and his foibles, was an education in itself. All who worked with him regarded him with admiration and affection." Nevertheless medicine demands the most rigid disciplines and so, casting aside personal considerations, I say my strongest conviction is that the commonest cause of "idiopathic" enlargement and dilatation of the œsophagus is failure of the cardiac sphincter to relax, and this syndrome merits the word "achalasia."

Rugby. R. E. SMITH.

CHLOROPHYLL AS DEODORANT

SIR,—The phrase "as dark as the inside of a cow" is traditional, and it is probable that our own insides are about equally dark though this does not have the authority of tradition. Photosynthesis, as the name implies, depends on light, and it is only after illumination that chlorophyll-containing systems are able to bring about the reaction between carbon dioxide and water that releases oxygen. Your suggestion (Aug. 23) that the alleged deodorising action of chlorophyll could be due to oxygen formation seems therefore a little improbable. Furthermore this action has not yet been brought about by isolated chlorophyll but only by fairly fresh chloroplast preparations.

But an explanation of the phenomenon might well be postponed until it is certain that there is a phenomenon to explain. Can no-one produce a statistically significant number of "second-best friends" on whom a proper experiment could be tried ?

Rothamsted Experimental Station,
Harpenden, Herts.
N. W. PIRIE.

SIR,—In your leading article you reproduce from the *News Chronicle* of July 30 a couplet to the effect that goats, in spite of the fact that they feed all day long on chlorophyll, tend to be odorous. Whilst we are not disputing this fact, we would remark that only water-soluble derivatives have been used as deodorants. Chlorophyll, as found in nature, is not water-soluble and it has to be specially processed in order to render it so. All the claims concerning the deodorant properties of chlorophyll have been based on this water-soluble variety.

Ashe Laboratories Ltd.,
Leatherhead.
L. DEADMAN
Chief chemist.

FUNCTIONAL DISORDERS OF THE SMALL INTESTINE

SIR,—With the increasing advocacy of the operation of partial gastrectomy in this country, functional disorders of the small intestine seem likely to become of importance, and it is good to see Dr. Morton Gill and Dr. Falle drawing attention to them in their article (Aug. 23).

In some people partial gastrectomy appears to uncover a latent tendency to a small-gut motility disturbance; in others the functional disorder undoubtedly precedes the formation of a peptic ulcer and is present before gastrectomy. In these unfortunates disastrous results are inevitable ; it behoves us to make sure before recommending operation that the motor function of the small gut is stable, especially if the patient is a woman.

Harrogate. A. J. GLAZEBROOK.

Obituary

JOHN GEOFFREY CUTTS

M.R.C.S.

Dr. Geoffrey Cutts, medical officer to the Northwood, Pinner and District Hospital, died in London on Aug. 18, from poliomyelitis, at the age of 37.

He was educated at Oakham in Rutlandshire, and at St. Mary's Hospital, where he qualified in 1940. After holding house-appointments elsewhere, he returned to St. Mary's as resident anæsthetist in 1942, and the following year he was appointed house-surgeon to the surgical unit at Harefield Chest Hospital. In 1944 he joined the Royal Navy, and he served as E.N.T. specialist in H.M. Hospital Ship *Tjitjilengka* in the Far East. At the end of the war he joined an old-established firm of general practitioners in Hatch End, and was soon appointed to the staff of Northwood Hospital.

W. R. writes : "Northwood Hospital is one of those centres where general practitioners work together as a happy team and, thanks to his early training in anæsthetics and E.N.T. work, Cutts proved himself a most accomplished specialist in both those departments. Not a man to be hurried, he showed dignity and a steady approach to his work. A little shy, slightly stubborn, he never jumped to hasty conclusions or reached a decision without careful thought. The best time to see him was at a difficult obstetric case. It is there that patience may be a supreme gift, and Geoffrey Cutts possessed it more than most of us. In the last few years of difficulty and transition he acted as secretary to the medical staff with conspicuous success. Good general practitioners are not born every day, and we have lost one of the best of them at a tragically early age."

Dr. Cutts leaves a widow and two young children.

Births, Marriages, and Deaths

BIRTHS

GOLD.—On Aug. 28, at South Hill Farm, Eastcote, Pinner, to Betty wife of Dr. Stephen Gold—a son.

HARDMAN.—On Aug. 28, at the Churchill Hospital, Oxford, to Philippa (née Woolf), wife of Dr. Maurice Hardman—a son.

WOLFE.—On Aug. 30, at *University College Hospital*, London, W.C.1, to Lesley (née Fox), wife of Mr. H. R. I. Wolfe, M.S., F.R.C.S.—a son.

DEATHS

HUNNARD.—On Aug. 30, at Dulwich Wood Avenue, London, S.E.19, Arthur Hunnard, M.B. Lond., aged 81.

HUNTER.—On Aug. 27, Charles Stewart Hunter, L.R.C.P.E., D.P.H., F.R.S.E., of 12, Beemead Avenue, Streatham, S.W.16, late of Darvel and Carnoustie.

STEPHENSON.—On Aug. 26, at West Haddon, William Arthur Stephenson, M.R.C.S., aged 84.

Notes and News

CAPITAL EXPENDITURE ON HOSPITALS

In calling on hospital authorities to submit capital estimates for 1953–54, the Ministry of Health announces (R.H.B. [52] 97) adjustment of the previous formula, particularly to help those regions where the need seems to be greatest. Boards are to submit estimates, within their allocations, which are to be in gross figures of which boards will be authorised to spend 80% during the year. The additional percentage has been included to allow greater flexibility within the programme. The following are the allocations to regional boards in 1953–54:

Region	*£000*
Newcastle upon Tyne	526
Leeds	475
Sheffield	721
East Anglia	248
North-west Metropolitan	600
North-east Metropolitan	468
South-east Metropolitan	499
South-west Metropolitan	787
Oxford	235
South Western	429
Birmingham	715
Manchester	681
Liverpool	325
Welsh	478

To boards of governors the allocation will be in the range of £40,000–80,000 for undergraduate teaching hospitals and of £10,000–35,000 for postgraduate teaching hospitals.

Boards are to assume that the allocation for 1954–55 will not be greater than that in 1953–54. The Ministry draws attention to the urgent need to increase the provision for mentally ill and mentally defective patients. It also suggests that boards, in planning their capital programme, should have particular regard for works which may bring about some decrease in maintenance costs. The Ministry will continue to make special provision from a central reserve for certain large schemes that are now being carried out.

SENIOR REGISTRARS IN THE NORTH-WEST METROPOLITAN REGION

According to the Ministry of Health's revised allocation, this region is to have substantially fewer senior registrars than at present. The regional hospital board has accordingly been considering how they can most fairly cut their coat to fit their cloth. They have decided to give notice to all the senior registrars now under contract with them, to take effect on March 31, 1953. Before that date the reduced number of posts will be readvertised and all the present senior registrars will be free to apply for them.

The board also proposes to appoint a number of "assistant physicians" and "assistant surgeons."

> The holder of one of these posts will have the status of consultant and be on the consultant salary scale, but he will be attached to a particular firm. He will have his own beds but the general scope of his responsibility will be outlined by the head of the firm. The appointment will be on a whole-time basis for five years with the option of transferring to a part-time appointment for the maximum number of sessions at the end of that period.

The senior administrative officer assured the board that he had received from the chairman of the Joint Committee of Consultants and Specialists and the Royal Colleges a verbal assurance that these proposals were acceptable to them.

The board has agreed to a proposal made by the board of governors of St. Mary's Hospital for an interchange of senior registrars, between selected regional hospitals and St. Mary's Hospital. For the present it is suggested that six senior registrars in medicine and six senior registrars in surgery should spend two years of their appointments at St. Mary's Hospital and two years in regional hospitals. The following regional hospitals have been asked to take part in the scheme: Paddington Hospital, Ashford Hospital, and West Middlesex Hospital.

Royal College of Obstetricians and Gynæcologists

Prof. Miles H. Phillips is to deliver the William Meredith Fletcher Shaw lecture at 1, Wimpole Street, London, W.1, at 2.45 P.M. on Friday, Sept. 26. He will speak on Percivall Willughby's *Observations* in Midwifery.

Institute of Laryngology and Otology

On Friday, Sept. 12, at 5 P.M., at the institute, 330, Gray's Inn Road, W.C.1, Dr. Norton Canfield, of Yale University, will open a discussion on the Analysis of Clinical Hearing Records.

Royal Institute of Public Health and Hygiene

On Wednesday, Oct. 15, at 4.30 P.M., Dr. W. D. M. Paton will deliver the Bengue lecture at the institute, 28, Portland Place, London, W.1. He is to speak on the Uses of the Methonium Compounds.

Postgraduate Courses for General Practitioners at Cambridge

During 1952–53 a series of one-day symposia for general practitioners *will be held* on Saturdays at Addenbrooke's Hospital, Cambridge. Each symposium will consist of three to five lectures or lecture-discussions and demonstrations of clinical cases or modern methods. The following programme has been arranged: nervous diseases (Oct. 25); obstetrics and gynæcology (Nov. 22); surgical diagnosis and minor surgery (Dec. 20); radiotherapy (Jan. 24); dermatology (Feb. 28); orthopædics and fractures (March 28); cardiovascular diseases (April 25); common fevers (May 30); pædiatrics (June 27); diseases of the ear, nose and throat (July 25): diseases of the eye. Further information may be obtained from the secretary of the Medical School, University of Cambridge.

British Postgraduate Medical Federation

On Tuesday, Oct. 7, at 4.45 P.M., at the Senate House of the University of London, Malet Street, W.C.1, Prof. J. Z. Young, F.R.S., is to give the opening lecture of the 1952–53 course on the Scientific Basis of Medicine. He is to speak on the Influence of Language on Medicine.

King's College Hospital, London

Dr. F. M. R. Walshe, F.R.S., will deliver the opening address of the session at the medical school, Denmark Hill, S.E.5, on Friday, Oct. 3, at 3 P.M. The annual dinner of past and present students will be held at the Savoy Hotel, W.C.2, on Saturday, Oct. 4, at 7.45 P.M.

University College Hospital, London

On Tuesday, Oct. 7, Sir Wilson Jameson will deliver the opening address of the session at the medical school, University Street, W.C.1, at 2.50 P.M. A course of postgraduate demonstrations for old students of the hospital will be given at the hospital on Oct. 30 and 31. Dr. F. M. R. Walshe, F.R.S., will take the chair at the annual dinner, which is being held at the Savoy Hotel at 8 P.M. on Oct. 31.

Barclay Prize

The late Dr. A. E. Barclay bequeathed £1000 to the *British Journal of Radiology*. The council of the journal has decided to use this bequest to offer a Barclay prize. The prize will normally be awarded annually to the author of the best account of original work in diagnostic or experimental radiology.

> The first award will be made in 1953, and candidates should inform the e[illegible] essay, with a brief indication of [illegible] han Sept. 30, 1952. The closing [illegible] 31, 1952. Further particulars [illegible] etary, 32, Welbeck Street, London, W.1.

Prescriptions in July

The Ministry of Health announces that in England and Wales during July the number of prescriptions declared to be submitted was 15,326,000, which was a decrease of 5·5% on the total for July, 1951. The number of forms declared to be submitted was 9,127,000 (decrease 11·6%); and the ratio of prescriptions to forms was 1·68 (1·57 in July, 1951). This year prescriptions for July were 909,000 more than in June. In 1951, July prescriptions were less than in June (as is usual); the difference was about 833,000.

Remuneration of General Practitioners

For the quarter ending Sept. 30, 1952, practitioners are to receive remuneration at the same rate as under the old arrangements together with a provisional supplement, proportional to the first amount, from the money made available by the Danckwerts award (E.C.O. 68/52). It is proposed to apply the same method of payment to the quarters ending Dec. 31, 1952, and March 31, 1953. The sum which has been paid into the central pool as a result of the Danckwerts award is at present provisional. It will be finally determined after March 31, 1953, and any necessary adjustments to the amounts already paid to executive councils will be made then.

As an interim measure the drug capitation fee is to be increased from 6*s.* 6*d.* per annum to 9*s.* 9*d.* with effect from April 1, 1952.

Congress on Rheology

The second International Congress on Rheology will be held at Oxford from July 26 to 31, 1953, under the presidency of Sir Geoffrey Taylor, F.R.S. Further particulars may be had from Mr. G. W. Scott Blair, D.SC., the University, Reading.

London College of Osteopathy

A postgraduate course for registered medical practitioners to be held at the college will begin in October. Further particulars may be had from the secretary of the college, 25, Dorset Square, London, N.W.1.

Pakistan Medical Association

Pakistani doctors in this country have formed a United Kingdom branch of this society. The following office-bearers have been elected: president, Dr. S. D. Jouhar; secretary and treasurer, Dr. M. Shafi (19, Bernard Street, London, W.C.1); committee members, Dr. T. H. Moghul, Dr. A. M. Akram, Dr. K. Y. Ansari, Dr. Saif-ud-Din Ahmad, and Dr. Mohd Abdul Rashid.

International Congress for Microbiology

The sixth International Congress for Microbiology will be held in Rome from Sept. 6 to 12, 1953, under the presidency of Dr. V. Puntoni. Further particulars may be had from the secretariat of the congress, Istituto d'Igiene (G. Sanarelli), Città Universitaria, Rome.

Course on Rehabilitation in Scandinavia

A group-training course on the Rehabilitation of the Adult Disabled is to be held in Sweden, Finland, and Denmark from Sept. 8 to Nov. 8. It has been organised by Dr. Harold Balme under the auspices of the United Nations, the World Health Organisation, and the International Labour Organisation.

Control of Medical Man-power

Mr. A. Lawrence Abel has replaced Mr. J. B. Oldham as a representative of the Royal College of Surgeons on the Central Medical Recruitment Committee for England and Wales; and Sir William Marshall has replaced Mr. Thomas Hunter as a representative of the Scottish Executive Councils' Association on the Scottish Central Medical Recruitment Committee.

Orphans' Pensions and Children's Allowances

In view of the increase in the family allowance rate to 8*s.* a week, the Minister of National Insurance has made regulations (1952 S.I. no. 1559. H.M. Stationery Office. 3*d.*) adjusting benefits for children payable under the old Contributory Pensions Acts. People receiving an orphan's pension or child's allowance and having at least two children in the family should inquire from the local national insurance office whether they are eligible for an increase. The regulations do not affect orphans for whom a guardian's allowance or industrial death benefit is in payment.

Unusual Foods for Human Consumption

The Nutrition Society is holding a conference on this subject at Bedford College, London, N.W.1, on Saturday, Oct. 18, at 10.15 A.M. The following papers are to be read: Seaweeds and their Value in Food-Stuffs (W. A. P. Black); Mushrooms and Toadstools (J. Ramsbottom); Insects as Food (W. S. Bristowe); Indigenous Foods of Central America (F. Aylward); Diet of Canadian Indians and Esquimeaux (H. M. Sinclair); Food of Australian Aborigines (G. H. Bourne); Protein in the Diet of the Isoko tribe of the Niger Delta (B. M. Nicol). Further particulars may be had from the programmes secretary, Mr. R. J. L. Allen, Monkhouse & Glasscock Ltd., Snowsfields, London, S.E.1.

Present Problems in Nutrition Research

The International Union of Nutrition Sciences is holding a symposium on this subject at Basle from Oct. 1 to 4. The speakers will include: Dr. J. Trémolières (Paris), Prof. A. I. Virtanen (Helsinki), Dr. D. P. Cuthbertson (Aberdeen), Prof. E. Crasemann (Zürich), Prof. E. J. Bigwood (Brussels), Prof. K. Lang (Mainz), Prof. K. Bernhard (Basle), Prof. K. Thomas (Göttingen), Prof. O. Högl (Berne), Prof. E. Abramson (Tomteboda, Sweden), Mr. S. J. Folley, D SC., F.R.S. (Reading), Prof. A. B. L. Beznák (Birmingham), Mr. L. J. Harris, D.SC. (Cambridge), Prof. H. Dam (Copenhagen), Prof. H. D. Cremer (Mainz), Prof. V. Demole (Lausanne), Dr. W. R. Aykroyd (F.A.O., Rome), Prof. A. G. van Veen (F.A.O., Rome). Further information may be had from the secretariat, c/o *Experientia*, Verlag Birkhäuser A.G., Basle, Elisabethenstrasse, 15, Switzerland.

Medical Mycologists

The committee on medical and veterinary mycopathology of the International Association of Microbiologists has compiled an international address list of medical mycologists. Copies (1*s.*) may be had from the Commonwealth Mycological Institute, Kew, Surrey.

No. 2 (Br.) General Hospital

The sixth reunion dinner of this hospital will be held at Simpson's Restaurant, Strand, London, W.C.2, on Saturday, Oct. 4. Tickets may be had from Dr. J. H. Easton, 25, Biddenham Turn, Bedford.

Graduated Beakers for Injectable Fluids

A new British Standard has been published (B.S. 1847:1952) for graduated beakers for injectable fluids (for hospital use). This specifies graduated heat-resistant glass beakers of 50 ml., 100 ml., and 300 ml. capacity. Copies of the standard (price 2*s.*) may be obtained from the British Standards Institution, Sales Branch, 24, Victoria Street, London, S.W.1.

King Edward's Hospital Fund are now issuing a second edition of their series of catering circulars. The following are available: Use of the Meat Ration, Care of Catering Equipment, Layout and Design, Sources of Waste in Catering, and Rations and Rationing. The circulars are issued free to hospitals, and copies can also be obtained (1*s.* post free) from the offices of the Fund, 10, Old Jewry, London, E.C.2.

During September Dr. Earl R. Loew, professor of physiology in Boston University School of Medicine, is acting as guest professor in the department of pharmacology and therapeutics, St. Andrews University Medical School, Dundee.

Prof. Robert [illegible] mas Anderson, and Dr. W. C. Cockburn are [illegible] ing September, under the [illegible] of the World [illegible] conduct refresher courses in the control of [illegible] at the main medical centres there.

The headquarters of the Ministry of National Insurance are now at 10, John Adam Street, London, W.C.2 (Telephone: Whitehall 9066).

Appointments

BARBER, J. M., M.D. Belf., M.R.C.P.: consultant physician, Ards Hospital, Newtownards and Bangor Hospital, Bangor.

BATES, J. L., M.B. Lond., M.R.C.P., D.P.M., D.C.H.: asst. psychiatrist (S.H.M.O.), Borocourt Institute for Mental Defectives, near Reading.

BULSTRODE, J. C., M.R.C.S., D.M.R.: consultant radiologist, Princess Elizabeth Hospital, Guernsey.

DE FONSEKA, C. P., M.B. Ceylon, F.R.C.S.: surgical registrar, Bath group of hospitals.

EDGCUMBE, J. O. P., M.A., M.D. Camb.: consultant pathologist, Exeter clinical area.

EDWARDS, C. H., M.R.C.P.: clinical asst. (part-time), department for nervous diseases, St. Mary's Hospital, London.

FITZMAURICE, W. J., M.B. Birm.: appointed factory doctor, Alcester district, Warwickshire.

GUILD, Euphemia, M.B. Edin., D.P.H.: asst. school M.O., Huddersfield.

JONES, H. M., M.B. Lond., F.R.C.S., D.L.O.: part-time consultant in otolaryngology, Royal Eye and Ear Hospital, Bradford.

MAITLAND, D. R., M.B. Edin., F.R.C.P.E., D.D.R.: consultant radiologist, radiological department, Royal Infirmary, Edinburgh.

MULHALL, P., M.B. Dubl.: asst. che [illegible] and [illegible] ors Radnorshire area, with clinical [illegible] Sanatorium and the Adelina Patti [illegible]

SINCLAIR, W. W., M.B [illegible]

STEWART, I. S., M.D. I [illegible] the Bingley, Keig [illegible] at the Hospital, [illegible] Grassington.

ZALESKI, WITOLD, M.B. Polish School of Medicine, Edin.: asst. psychiatrist (S.H.M.O.), Pewsey Hospital for Mental Defectives.

University College Hospital, London:

GREAVES, D. P., M.B. Sheff., F.R.C.S., D.O.M.S.: consultant ophthalmic surgeon.

KINGDOM, L. G., M.B. Camb., F.R.C.S.: consultant E.N.T. surgeon.

POND, D. A., M.D. Camb., M.R.C.P., D.P.M.: consultant physician, department of psychological medicine.

East Anglian Regional Hospital Board:

JUBY, H. B., M.B. Lond, D.L.O.: E.N.T. registrar, Norfolk and Norwich Hospital.

SUTTON, P. H., M.D., B.SC. Lond., M.R.C.P.: consultant chest physician, Norwich area chest clinic.

PROGRESS IN THE TREATMENT OF BREAST CANCER*

D. W. SMITHERS
M.D. Camb., F.R.C.P., D.M.R.
PROFESSOR OF RADIOTHERAPY IN THE UNIVERSITY OF LONDON AT THE ROYAL CANCER HOSPITAL

I HAVE chosen the subject of Progress in the Treatment of Breast Cancer for several reasons, chiefly because it was this disease which prompted the foundation of this lecture, but also because it provides a good illustration of the theme, within the general title laid down, which I think most requires discussion at the present time. This theme is the need for a return from the "universal cause and cure" attitude, which has inspired so much experimental cancer research and has widely infected the medical profession, to the clinical view of the human problem which it really is. We are in danger of becoming bemused by a wealth of disconnected and impressive scientific detail into believing that the research-worker is nearer to the problem than the doctor, when the reverse is the case.

The clinical view, however, needs to be revitalised so that advancement in knowledge may find a practical expression helpful in prevention and treatment. The oversimplified clinical view which has so long been the basis of our treatment methods has led us into a far too rigid and largely false division of cancer patients into those in whom we must make as rapid and as drastic an attempt at cure as possible, and those whom, because we regard the situation as hopeless, we abandon either to a half-hearted attempt at palliation or to the quacks who provide the encouragement we fail to give.

On Progress

Halsted looking back in 1897 concluded that up to that time no woman with breast cancer had ever been cured. There are those today who think that not only was he right then but that there has been little fundamental change in the situation since his time. They wave aside our survival-rates, the evidence which their predecessors in scepticism had demanded from us, point to our failure to make a drastic reduction in the general breast-cancer death-rate, assure us that there are no grounds for our fond belief that the earlier we give our treatment the greater the chance of cure, and assert that those patients whom we so carefully pick out to treat would live as long if we did nothing. These people are not clinicians, not theirs the daily decision of what to do for Mrs. Jones who has arrived with a frightened husband, an anxious daughter, and a lump in the breast. They are pathologists, hygienists, biometricians, and statisticians, the pyrrhonists of medicine whose facts are not regularly warmed by compassion. It is most important that we listen because we may learn. They will at least keep us from complacency, though those of us who regularly deal with cancer patients are not lightly to be accused of this failing. We may, however, comfort ourselves with the assurance that their figures do not contain the whole of truth and that they are in some danger of coming to know the significance of everything and the value of nothing.

If we are to allow ourselves to speak of progress we must take a realisatic view of the past, examine the basis for our present beliefs and practice, and plan the future so as to promote the best interests of our patients and not those of surgery, radiotherapy, chemotherapy, or even the Registrar-General's annual report.

RELIEF OF SUFFERING

In looking back over the past for signs of progress I would put first relief of suffering. This is not something we can arrange on a table or fit into a chart. Surgery removes the anxiety of the presence of a lump in the breast, and, as judgment has improved, has continued to prevent the discomfort of ulceration while steadily reducing the incidence of local recurrence. We cannot compute a figure to express the value of hope supplied or of relief from the worry, pain, and distress which would have gone with the steady local advance of a tumour. We cannot put these benefits into a survival-rate for patients who develop distant metastases and live no longer than they would have done untreated. Surgery, looking back over the years, has solid cause to congratulate itself on the relief of suffering it has achieved for patients with breast cancer.

Radiotherapy in its comparatively short life has already established a claim to be considered the most valuable means of palliation at our disposal for patients with malignant disease. It assays one of the most difficult tasks in medicine. It is confronted daily by human tragedy which makes incessant demands for cheerful reassurance or gradual enlightenment—demands that tax our humanity, understanding, and ingenuity to the full. It requires an acquaintance with a wide field of clinical medicine and the ability to work closely, harmoniously, and often most unselfishly, with many different surgeons. The safety of the patients and of the workers in these departments, as well as the efficient conduct of treatment, cannot be assured without a high degree of technical proficiency in a complicated branch of applied science. The degree of progress in the relief of suffering of patients with breast cancer for which it has been responsible can be appreciated at once if we consider how we should now get along without it in those hospitals where hundreds of these patients present themselves for our help each year.

Surgical castration was used before X rays were discovered; ovarian irradiation has been employed for thirty years; and hormone treatment has for the past fourteen years come to join surgery and radiotherapy in the treatment of breast cancer patients. After all this time we are still uncertain about their future possibilities. We can, however, see relief obtained quite dramatically at times which was not obtainable before, and is still not obtainable by any other means. Great interest is aroused by the chance to influence disseminated tumours either directly or by alterations in the environment in which they grow. The possibility of learning more about the control of growth and of adding to the efficiency of our tumour treatment methods that hormone therapy has provided is a spur and a challenge.

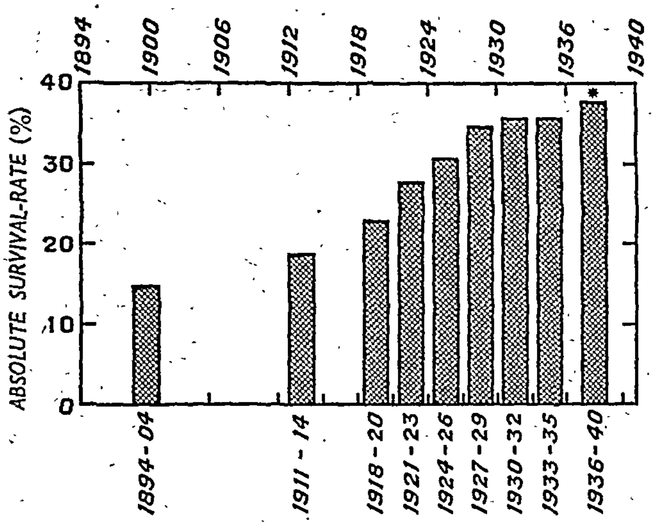
All this I regard as good evidence of progress.

LONGER SURVIVAL

I have taken relief of suffering first because it seems to me to be one of the chief duties of medicine; but we like to think that we save life and persist in judging our efforts by the sometimes dubious criterion of survival. The only continuous record of survival of all new patients with breast cancer attending one hospital since the introduction of serious attempts at treatment that I know of is that of the Massachusetts General Hospital (Taylor 1949). This remarkable record is almost complete from 1894 to 1940 (fig. 1). If we place these results in a time relationship with those obtained in other hospitals where all new patients seen, whether treated or not, have been included, we can see that it is a fair representation of the state of affairs in such centres

---

* The First Dorothy Platt memorial lecture, given at King's College Hospital Medical School on July 1, 1952. This lecture was established by the late Mr. J. B. Hunter, to whom Miss Dorothy Platt gave a donation to be used for the advancement of the knowledge of cancer.



*The figure of 38% for 1936–40 is based on the assumption of an operability-rate of 75% for those years, it having varied from 71% to 80% during the preceding 40 years and the total new cases seen for 1936–40 not being in the text.

Fig. 1—Results of treatment in patients with cancer of the breast attending the Massachusetts General Hospital from 1894 to 1940, calculated from the "total primary cases."

(fig. 2). What it shows is that the survival-rates of all patients with breast cancer seen in certain hospitals which report their entire material, in several countries, has markedly improved. It does not show that such an improvement has been general and it does not show that the improvement has been due to the treatment given. These survival-rates are obtainable from only a few centres, and they are the ones, as shown by their interest in recording and by the knowledge of their results which they have had to guide them, in which improvement in treatment is likely to have occurred, but also, because of their reputation, to which an increasing proportion of earlier cases is likely to have been referred. It does show that in such centres the chance that a patient attending with breast cancer will survive five years has probably been more than doubled in the last thirty years.

This improvement could be due to a number of things. It could be due to a change in the selection of patients attending the hospitals which record their results; it could be due to a change in the type of tumours developing, with a swing towards a less malignant character; it could be due to an improvement in speed of diagnosis and in time of starting treatment; it could be due to an improvement in diagnosis resulting in the inclusion of more less-malignant tumours in the total recorded by adding some which had previously either been missed or regarded as non-malignant; it could be due either to improvement in the methods of treatment themselves or to a better selection of treatment method for each individual patient; lastly, it could be due to some combination of these factors.

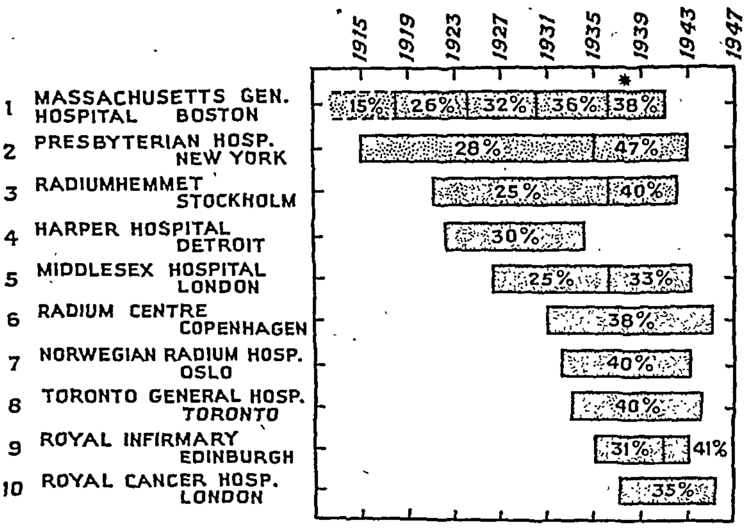
Change in Malignancy of Tumours

It would be difficult to prove or disprove that the character of breast cancer has changed with the years, tending to become less malignant. Histological grading does give an indication of malignancy, but if we were to try to assess such a trend by comparing the proportions of cases in each histological grade from time to time we should be confused by differences in grading methods and skill and, even more important, by differences in the proportions of tumours graded. Since accurate grading is not possible with small pieces of tumour it can only be done on operable patients whose tumours are heavily weighted towards the more differentiated. Since grading is an arbitrary division into sections of a continuous spectrum of degree of differentiation, usually arranged to have a large central group with smaller groups on either side, it is not easy to observe any gradual change merely by listing from time to time the proportion found in each.

The degree of clinical advancement of the disease at the time the patients are first seen is in part a reflection of the malignancy of the tumours concerned, and the fact that the operability-rate at the Massachusetts General Hospital has not changed in [illegible] years suggests that there has been no marked trend towards a diminution in malignancy. An improvement in stage distribution has occurred, however, in some other centres, notably Radiumhemmet, corresponding with their improvement in results, and it is debatable how far such trends may be due to earlier diagnosis, better selection, or alteration in character of the tumours. There does not seem to be any real evidence on which we would be justified at present in making the assumption that the character of breast cancer is changing.

Improved Diagnosis

Improved diagnosis may have resulted in the inclusion of some patients omitted altogether in the past, or some tumours previously regarded as non-malignant. If so, there may have been a change, not in the nature of the disease, but in the selection of an increased proportion of more favourable cases in the groups reported. Certain benign lesions of the breast may simulate cancer—e.g., ad[illegible] fat necrosis, tuberculous mastitis, the b[illegible] named granular cell "myoblastoma," and plasma-cell mastitis—and some circumscribed carcinomas may be mistaken for be[illegible] tumours or cysts. On balance improved diagnosis should tend to detect and so [illegible]



*On the assumption that the operability-rate has not changed and that the total number of new patients seen during this period was 527.

Fig. 2—Variation of absolute survival-rate with date of treatment in patients with cancer of the breast.

ore non-malignant tumours which might have been cluded in the past, than discover and so include alignant tumours which might have been omitted.

An important influence here might be a real change of pinion about a group of tumours formerly regarded s benign and now thought of as malignant. I know f no such general swing of opinion in breast cancer, hough there are considerable differences in interpretaon between pathologists, particularly with regard to the ividing line between duct papillomas and duct carciomas. There does not seem to be good evidence that nproved methods of diagnosis have increased the roportion of the less malignant tumours in the patients ecorded as having breast cancer though it would be ifficult to show that this were not so.

eduction of Delay in Starting Treatment

Those who are most persistent in telling us that there s no evidence of improvement in survival due to treatment also maintain that early diagnosis makes no difference to the prognosis. This is not so. Prognosis robably depends more on the type of tumour that a atient develops than on any other factor since this so rgely determines the degree of advancement of the isease by the time the patient starts treatment (see able). Patients with slow growing breast tumours may resent themselves at hospitals for the first time having oticed a lump for many months and still survive for any years after treatment. A group of patients with ng histories will in fact contain a high proportion with e less malignant tumours, since if they had developed ore malignant ones at the same time and had had no eatment they would have been dead. With the more alignant tumours early treatment is of great importnce. Many will have metastasised before the patient first seen but the sharp deterioration which occurs survival time with histories of three months or more an indication of the importance of speed in this group.

Unfortunately there is not much real evidence of any cline in the period of delay which occurs between ticing the first symptom and starting treatment. gures giving the change in average delay do not give clear picture of the important issue, since it is only ring the first two or possibly three months that delay of much importance. Quite a few patients with a od prognosis and histories of two, three, or more ars may well produce a misleadingly high figure for the erage delay.

anges in Selection of Patients

The selection of patients attending the hospitals ere complete records are kept and where results are blished may well account for the differences in survivales between them. To see if it may not have accounted the improvement in results over the years within one hospital we need evidence that this improvement has not merely followed a change in stage distribution. We have just seen that there has been no change in operability-rate at the Massachusetts General Hospital in fifty years. At other centres the position is different; at Radiumhemmet for instance the proportion of early cases increased from 50% to over 70% for the periods 1921–35 and 1936–41. In my own hospital there has been no steady change in the stage distribution, but since 1937 there have been fluctuations from year to year. A decline in the percentage of early cases during the first war years was clearly reflected in a corresponding fall in survival-rate (fig. 3). Definitions of staging and of operability are sadly lacking in uniformity, and comparisons are most difficult. It is clear, however, that the results obtained are closely dependent on the material treated and that alteration in this alone may well account for much of the change in survival-rate which, when it moves in the right direction, we attribute to our therapeutic skill.

IVIVAL OF PATIENTS WITH OPERABLE BREAST CANCER CCORDING TO AXILLARY LYMPH-NODE INVOLVEMENT AND RADE OF MALIGNANCY OF TUMOUR

sed on 482 patients seen at the Royal Cancer Hospital, 7–1950 for whom the necessary details were recorded. Graded by Dr. M. Thangavelu.)

ade	Lymph-nodes not involved		Lymph-nodes involved		Proportion of patients with lymph-nodes involved

*According to whether untraced patients are regarded as alive or dead.

Fig. 3—Results of treatment of patients with cancer of the breast at the Royal Cancer Hospital set in relation to variation in proportion of patients in early stages.

A DOWNWARD TREND

There are a number of reasons why there has been no great fall in the general mortality-rate from breast cancer. It is not in itself an argument against treatment having improved in the better centres, since they deal with only a small proportion of the total and since no more than a gradual and limited improvement can be expected with existing methods. There are also difficulties with death certification since the tendency to record death as due to breast cancer in any patient who has once had the disease is so strong. Until 1940 in fact, the Registrar-General's office often changed the recorded cause of death to cancer when this was mentioned as a subsidiary cause by a doctor who had himself attributed the death to something else. It is going to be difficult to judge the effect of treatment by changes in mortality-rates if we are never going to let a patient who has once had breast cancer die of anything else. With all these difficulties, however, if a correction is made both for the growth of the population and its increasingly adverse age composition a slight downward trend in mortality-rate for England and Wales appears.

Survival without Treatment

Accurate data on the duration of life in patients with untreated breast cancer would be most valuable. The published work agrees in suggesting that the average time from first symptom to death is about three years.

Probably many variables may influence the expansile auricular pulsation. Elkin et al.[2] suggest that the following factors are relevant: left auricular size, flexibility and elastic stretch of the auricular wall, rate of auricular diastolic filling from the pulmonary veins, presence of mural thrombus, irregular rhythm, transmitted thrust from a vigorous right auricular expansion in tricuspid incompetence, and the systolic contracting impulse of a hypertrophied right ventricle. Of their 29 patients with mitral stenosis who showed this radiological sign 14 had no systolic murmur and only 8 were thought on clinical evidence to have mitral incompetence. All 29 patients underwent valvotomy; and in 5 of the 14 without systolic murmurs mitral incompetence was proved at operation by a palpable regurgitant jet on the surgeon's finger. This finding was evidently related closely to the blood-pressure level recorded at the time of operation—an interesting observation that deserves further attention. Elkin et al. noted that the regurgitant stream was stronger when the blood-pressure was higher, and its absence in some cases, with a valve not necessarily fully competent, could be explained by diminished ventricular strength at the time.

The anomaly in mitral stenosis of systolic auricular expansion, seen radiographically, unaccompanied by a systolic murmur has been carefully studied by Froment et al.[3] who believe that "auricular retropulsion" contributes to this paradox. Six patients with a calcified valve were observed fluoroscopically; each was in sinus rhythm, and their left auricles were only moderately dilated. In ventricular systole the mitral valve moved—contrary to the physiological direction—towards the auricle. It thus seemed probable that in certain "mitral" hearts, particularly perhaps those in which the principal mass was formed by a turgid auricle containing $^1/_2$–1 litre of blood, the physiological movement of the auriculoventricular septum was reversed, with the ventricle firmly anchored at its base. It is, then, this recoil of the auriculoventricular septum, moving piston-like inside a cavity obstructed by the narrowed mitral valve, that may give the impression of systolic expansion, whether or not a ventriculo-auricular reflux is superadded. Retropulsion with apparent systolic auricular expansion, Froment et al. conclude, is essentially, if not exclusively, a sign of mitral endocarditis with auricular stasis, and is not strictly indicative of mitral insufficiency; in prognosis it may have some value.

After a lapse of many years mitral incompetence once more becomes a fashionable diagnosis. Many views were expressed recently at the European Congress of Cardiology held in London, but there was general agreement that the pendulum of diagnosis is swinging back to the stethoscope. It is perhaps disappointing that no constantly reliable information has come from the many detailed studies employing cardiac catheterisation. Pulmonary capillary pressure curves often give a characteristic pattern, with fusion of the A, C, and V waves, and angiocardiograms show a lingering opacification of the left auricle, but no dependable clinical correlation can always be proved by these methods. The same criticism applies to electrokymography and also to the measurement of œsophageal pressures at the auricular level. Auscultation is on the whole the most informative single diagnostic approach.

In some patients with mitral disease, whose symptoms have justified cardiotomy, the surgeon has been surprised to find predominant valvular incompetence, rather than stenosis, when clinical indications have favoured the latter. Surgical relief seems to be equally necessary in such cases. The technical possibility of correcting the defect is discussed in this issue by Mr. Andrew Logan and Dr. Richard Turner. They successfully treated 15 patients by threading a pericardial strip through the wall of the left ventricle to provide a sling for the valve. The resulting improvement was not spectacular, and the authors are cautious not to overestimate the possibilities of this operation. Until we know more about the complicated mechanics of the mitral valve cusps, both in health and in disease, plastic surgery cannot have a standard place in treatment. Many valves, for example, are rigidly calcified, and in these cases mitral incompetence is commoner. There is an increasing danger that our enthusiasm for surgery in the treatment of mitral disease will divert attention from the prognostic importance of old myocardial damage, both auricular and ventricular, caused by the initial rheumatic inflammation.

RETAINED PLACENTA

Burton-Brown's radiographic study[1] of placental separation has shown that after normal delivery of the infant the uterus must contract further if the placenta is to be separated. Separation is usually, but not always, accompanied by retroplacental hæmorrhage. Alvarez and Caldeyro-Barcia[2] have observed the pressure changes in the ligated umbilical-cord vessels and found that normally contractions recur at the rate of 4 per 10 minutes and that the average time for physiological separation is 6 minutes.

In different hands management of the third stage of labour varies from cautious non-interference, except in the presence of hæmorrhage, to the administration of oxytocics during completion of the second stage in order to hasten separation of the placenta and minimise blood loss. Stern[3] interferes in the third stage only for hæmorrhage; and then he gives ergometrine and gently expresses the placenta, or removes this manually if necessary. When the third stage is prolonged without hæmorrhage, he does not interfere at all. Of 17,002 patients delivered at his hospital in 1947–51, only 395 (2·32%) had a third stage lasting over one hour; and of these 144 (0·85%) had no bleeding in this stage. In 13 patients the third stage lasted for more than twelve hours. There were no maternal deaths. Stern concludes that the danger of serious postpartum hæmorrhage after the first hour or two of the third stage is very slight; thus expression should not be attempted, since the danger of retention of the placenta is less than the risk of manual removal.

Hammond[4] accepts the evidence that the use of ergometrine before the third stage lowers the incidence of postpartum hæmorrhage, and believes that the risk of contraction ring with this drug has been exaggerated. On the other hand, he asserts that abnormal retention of the placenta, as reflected in the proportion of cases where manual removal is needed, may be increased: the reported rates with ergometrine are four to six times as high as the admirably low figure of 0·26% for manual removal in the Guy's Hospital series described by Hammond.

All agree that meddlesome manipulation of the fundus of the uterus is liable to disturb the third stage. The Credé manœuvre is perhaps in undeserved disrepute because it is sometimes practised without regard to Credé's directions that contraction of the upper segment and expression of the placenta into the birth canal should be secured before expulsion is attempted.

Furthermore, with manual removal, there is a definite risk of shock and infection, especially great in the debilitated and in patients with heart and lung disease.

Thus accounts of the routine use of ergometrine before separation of the placenta in large series of cases will be awaited with keen interest.

THE NEW MARTINDALE

It will be surprising if pharmacists and physicians all over the world do not feel their hearts strangely warmed by the sight of the 23rd edition of Martindale's *Extra Pharmacopœia*, volume I of which has just been published. Here indeed is one of the old familiar figures, clad in decent blue buckram, and embellished (though with restraint) by gold lettering. But he is fatter—more than four times fatter—than the poor creature born some seventy years ago; and this is partly because he has just made a meal of his even more aged competitor, Squire's *Companion to the British Pharmacopœia*.

Martindale is a book full of surprises, so that some readers may find themselves wishing that they had been introduced to it while they were students, when a thousand and one minor queries, too heterogeneous to take to any one of their teachers, went unanswered. Where else could they so conveniently obtain information on say 'Amesec,' anti-rust solution, and Wahoo bark (prescribable on form E.C.10)? And how else could they confirm that the doctor who declared his faith in Basham's mixture was really serious, even if misguided about its therapeutic merits?

Armed with Martindale, the medical practitioner can hope to contend with the increasing spate of proprietary preparations; and he will be delighted to find that the latest compound tablet is nothing more than two or three of his old *B.P.* friends in fancy dress. The materia medica of the *Extra Pharmacopœia*, running to more than 1000 pages, is derived not only from British publications but also from American and Continental sources. The admirable practice of interspersing the mass of pharmaceutical facts with therapeutic comment is preserved in this edition, and about 4000 original papers have been briefly abstracted for this purpose. On this subject, however, the editors sound a note of warning: "Since the *Extra Pharmacopœia* is a reference book on materia medica and not a textbook of therapeutics no attempt is made to offer authoritative assessments of the value of medicinal agents where this is the subject of controversy. The aim throughout is to give an unbiased presentation of the published work." This carefully worded statement goes far towards disarming criticism. Perhaps it also indicates a measure of uneasiness among the editors, who may occasionally wonder whether their zeal to serve both pharmacists and doctors invariably gives the best results. They would be the first to admit that the medical references represent a selection touching merely the fringe of a vast subject, and that undue importance may occasionally be attached to a publication simply because it is a recent one. If this is so, it may well be asked whether the book would not gain in value by the adoption of more exacting standards in the choice of references to illustrate the use of drugs.

Statements are made here and there which might be interpreted as guidance to the doctor when in fact the information is merely of historical interest. For example: "Garlic has expectorant, antiseptic, diaphoretic, and diuretic properties, and has been used as the syrup in the treatment of chronic bronchitis, phthisis, and other pulmonary conditions." But perhaps the argument in favour of developing a more critical therapeutic approach is most apparent in the therapeutic index. Admittedly this is only an index, and the reader must turn to the appropriate pages to see if any statements are made about the relative merits of the drugs listed. But could not this index be printed in such a way as to focus attention on the drugs which have been shown to be effective, and to minimise the importance of drugs which are now known to be useless or unreliable? For example, among a score of alleged remedies for travel-sickness should not hyoscine and dextrose be printed in bold type? Surely the mention of cerium oxalate merely confuses the issue. Again, under typhoid fever, we find chloramphenicol given the same prominence as anti-typhoid serum and sulphurous acid. The reference to sulphurous acid says: "It is seldom used internally but has been employed, freely diluted, in cholera, and has been given in typhoid in 20 to 30 m. doses . . . every two or three hours." If this serves any purpose at all, it is merely to make us understand why Osler became a therapeutic nihilist. These curious remnants are scattered through the text, and they seem out of place by the side of the admirable special sections on such subjects as antibiotics, antisera, blood-transfusion, and dangerous-drugs legislation.

If there is a good deal of chaff there is also—thanks to the exertions of the pure chemist and the pharmaceutical chemist—a great deal of wheat; and it would be difficult to imagine a pleasanter way of surveying the harvest than to browse through the *Extra Pharmacopœia*. Martindale is in fact unique; and all pharmacists and physicians will wish to have this extremely valuable book which has become indispensable in their work. Many members of the two professions will also wish to pay tribute to the editors who have worked with exemplary skill and tenacity to make this volume worthy of its numerous predecessors.

CHROMOBACTERIAL INFECTIONS

The chromobacteria are gram-negative, motile, nonsporing, and aerobic bacilli which produce various pigments in culture. They are usually considered to be non-pathogenic saprophytes. Their occurrence in association with human lesions was rarely recorded in the pre-antibiotic era, but the evidence suggests that such infections may be seen more often as a consequence of modern chemotherapy. In 1951 Wheat et al.[1] reported 11 cases of urinary tract infection caused by *Chr. prodigiosum* (*Serratia marcescens*); 2 of these patients also had septicæmia, and 1 of them died of endocarditis. Some form of mechanical interference with the urinary tract, such as catheterisation, cystoscopy, or a surgical operation, preceded the infection in every case; and though the source of the organisms was not determined, it seemed likely that they had been introduced in this way. The infecting organism invariably had a high resistance to penicillin, streptomycin, chloramphenicol, aureomycin, and terramycin, and the authors felt that the use of antibiotics, which eliminated all the organisms commonly responsible for urinary infections, had prepared the way for invasion by the chromobacteria.

Recently another fatal septicæmia caused by *Chr. prodigiosum* was reported by Patterson et al.[2] This case differed from those reported by Wheat et al. in two important ways. First, the septicæmia developed as a complication in a patient acutely ill with severe and repeated hæmorrhages from a penetrating peptic ulcer; the urinary tract remained sterile throughout. Secondly, the strain of *Chr. prodigiosum* isolated from the bloodstream was highly sensitive in vitro to streptomycin and neomycin, and partly sensitive to chloramphenicol, aureomycin, and terramycin. The septicæmia apparently began after 17 days of penicillin therapy, though a positive blood-culture was not obtained until the 29th day, when combined penicillin and aureomycin was being given. Thereafter various combinations of drugs were tried: aureomycin was given for 2 days, aureomycin and streptomycin for 4 days, streptomycin and chloramphenicol for 6 days, streptomycin alone for 1 day, streptomycin and intravenous aureomycin for

1. Wheat, R. P., Zuckerman, A., Rantz, L. A. *Arch. intern. Med.* 1951, 88, 461.
2. Patterson, R. H., Banister, G. B., Knight, V. *Ibid*, 1952, 90, 79.

6 days, and finally neomycin for 1 day; but the infection resisted all treatment, and when the patient died the blood-culture was still positive and there were signs of bronchopneumonia. Post-mortem examination was not possible; so little is known of any complicating lesions, such as abscesses or endocarditis, which might have diminished the response to chemotherapy. It is, however, surprising that in this patient the septicæmia was apparently unaltered in any way by any of the antibiotics given, even though the organism was at least partially sensitive to them all. As the antibiotics were often given in pairs, it is possible that antagonism between them, of the type reported by Jawetz and Gunnison,[3] reduced the effectiveness of streptomycin, to which the organism was most sensitive in vitro.

Reports of monilial infections complicating treatment with antibiotics are becoming more frequent,[4,5] and it may well be that the chromobacteria too will assume an importance hitherto unsuspected. Although many "local" types of infection with these organisms, in the urinary tract for instance, may heal spontaneously, clearly the results of systemic invasion are likely to be grave—a fact that must be accepted as another warning of the dangers of the indiscriminate use of antibiotics.

TUBERCULOSIS AND THE NURSE

As hosts to infective organisms we are far from cordial, and have a number of well-recognised gambits for making them not feel at home. Our relations with the tubercle bacillus, however, are ambiguous; for, though we cannot be said to like the fellow, we are less adroit than usual in getting rid of him. As Dr. F. A. H. Simmonds remarks, in a capable handbook[6] designed for the use of hospitals (and especially for medical superintendents, matrons, nurse teachers, and home sisters), though tuberculosis causes much ill health, so that time and effort must be spent in preventing it, it nevertheless affects most people only slightly. If we had means of detecting in advance those with poor resistance we should be saved a great deal of trouble; as it is, we must make do with the facts we have. We know, for instance, that nearly all of us encounter and get infected by the tubercle bacillus, not once in a lifetime but probably many times; and that a successful outcome turns on various factors—on inborn resistance, the increased immunity which follows a successfully resisted primary lesion, age, sex, race, and nutrition. It may also turn on the frequency of infection and the size of the dose; but here informed opinion is divided. Family contacts, especially children, of patients with active pulmonary tuberculosis are certainly more apt to develop the disease than otherwise comparable people; and they are almost bound to inhale tubercle bacilli more often, and in larger numbers, than other family groups. But the family with a tuberculous parent is often short of money, which may mean that the children are poorly nourished; and moreover they may have inherited a poor resistance to the disease. Again there is good reason to believe, Dr. Simmonds says, that the arrangement of the bronchial tree and the ciliary mechanism prevent large droplets from entering the lung; only small particles are likely to penetrate to the smaller bronchi, and even then only occasional particles are likely to get through. So even when an infectious patient coughs carelessly, only droplets carrying a small number of bacilli, or even a single bacillus, will ever be able to reach the pulmonary alveoli of a bystander, and then but rarely. Moreover, even a patient with advanced tuberculosis, when he coughs, expels only a few droplets carrying heavy infection: many contain none. In theory, indeed, it should be almost impossible to get oneself infected with tuberculosis by contact with an open case. On the other hand, we know it can happen.

The question of reinfection is equally confusing: for while some authorities hold that repeated reinfections are particularly dangerous, causing most pulmonary tuberculosis after the primary infection, others think that repeated small doses of reinfection may actually benefit the recipient by raising his immunity. Others, again, say that reinfection is impossible, and that tuberculosis arising after the primary focus has healed must always be due to the outbreak of latent infection.

All these factors and opinions must be taken into account when a programme is planned for the protection of nurses, medical students, almoners, physiotherapists, radiographers, laboratory technicians, ward-maids, young porters, and anyone else in the susceptible age-groups liable to encounter tuberculous infection in hospital. Dr. Simmonds recalls that the risk of infection may be greater in general hospitals, from unsuspected cases, than it is in sanatoria where precautions against infection are enforced; and his recommendations for the protection of staff apply equally to either kind of institution.

He insists that the nursing staff chosen should be healthy to start with, and kept healthy by proper care. The general clinical examination, on admission, should be supplemented by an estimation of hæmoglobin, by measuring the erythrocyte-sedimentation rate (to establish the normal rate for the individual), and by tuberculin tests, X-ray examination, and some psychological assessment of personality, not necessarily by means of tests. Periodical re-examinations should be made as a routine, so that they do not arouse alarm; and these should include weight records, and chest radiography at intervals of 3–6 months, especially in those still negative to tuberculin tests. Such negative reactors should not be put into wards or departments where tuberculosis is likely to be met. In his detailed instructions for applying tuberculin tests he lays stress on what should be accepted as a positive reading and what should not—an important point, since readings of the same results by different individuals often show considerable variety. Negative reactors, in his opinion, should always be given the opportunity of B.C.G. vaccination; for even if a nurse manages to avoid tuberculous patients during her student training she is unlikely to do so throughout her career. But the essence of prevention lies less, perhaps, in artificially produced immunity than in keeping the nurses's own defences in first-class trim—that is in keeping her well nourished, fit, and happy. Dr. Simmonds speaks tellingly of the value of good meals and plenty of them, eaten in congenial surroundings. Agreeable quarters, clubs and recreations, transport to town, and reasonable hours of duty are amenities which every hospital should provide, in order to safeguard the health—in some cases the lives—of its nurses.

ELECTRONIC STERILISATION

BIOLOGICAL and other preparations are apt to be damaged by thermal or chemical treatment; and thus sterilisation by high-velocity electrons is now attracting research-workers' attention. At a meeting recently convened by the Department of Scientific and Industrial Research it emerged that this method of sterilisation, *though likely to prove expensive, offers* great advantages: and in the U.S.A. it has already been shown to sterilise sutures and surgical dressings, blood-plasma, penicillin, cosmetics, and vaccines.

Electron accelerators with an effective anode voltage of the order of 2–3 million volts have been used. Such energies are not great enough to induce radioactivity in irradiated products. In general they kill large organisms more readily than small. At the Massachusetts Institute of Technology the sterilisation doses proved to be as follows: insects 100,000 units, vegetative bacteria 500,000 units, moulds and yeasts 1 million nits, and bacterial spores 2 million units; viruses and nzymes required 5–10 million units.

The cost of an electron generator capable of sterilising ton of product per hour would be £140,000, though the unning cost would be only 1½d. per lb. This high apital cost has stimulated interest in other sources of electrons, such as γ rays from by-products of the Atomic Energy Project; and it is estimated that a Co^{60} source costing £2000 would sterilise 7 lb. of product per day at a cost of 1s. per lb.

COSMETICS AND THE SKIN

"Hypoallergic" cosmetics are much advertised in the United States; so perhaps cosmetic dermatitis is commoner there than in this country. Possibly cosmetics are used more freely in America; or they may contain a greater number of potentially sensitising substances; or a larger proportion of the people who use them may have a relatively lower threshold for sensitisation. But even in this country, cosmetics, jewellery, and clothing are common enough irritants, for they come third after occupational hazards and plants as a cause of dermatitis. Moynahan[1] says that permanent-waving reagents give most trouble, but Garnier and Marshall[2] believe that the hair dye, *p*-phenylenediamine, and similar compounds are most often responsible. Lipsticks and nail varnish come next, while face creams and powders are rare offenders, though occasionally they contain perfumes or orris or rice powder which may produce a dermatitis.

Permanent-waving compounds and depilatories are primary irritants, attacking the keratin chemically and breaking down disulphide linkages. The keratin of the skin cannot be expected to escape when the keratin of the hair is thus attacked. Oxidation dyes of the "para" type are also primary irritants, and so are alkalis used for various purposes. Most of the other substances act as sensitising agents.

Dermatitis from *p*-phenylenediamine may occur after the first or after any subsequent application. A negative patch test, although a guide, does not exclude all risk: a trivial scratch may be the focus from which the exuding dermatitis starts, and no amount of warning on the package can eliminate the risk of dermatitis from an abrasion received after the hair has been dyed. *p*-Phenylenediamine can cause such a severe dermatitis that its use should be strongly discouraged, or even abandoned, like that of the highly toxic metallic dyes of the past. In the permanent-waving process keratin disulphide linkages are broken down and re-formed, but, if the process is overdone, it may become irreversible. Dermatitis may arise from heat or from the chemicals used. If the hair is bleached soon afterwards or, worse still, dyed, waved, and then (when the result proves unpopular) decolorised again, the long-suffering linkages may collapse and the hair break.

Lipstick dermatitis may be caused by sensitisation to one of the ingredients or to the development of light-sensitivity from the photodynamic substance, eosin. Only a few individuals are susceptible to eosin, and not all forms of eosin are equally harmful, so that relief may be obtained by changing to a lipstick containing another form of eosin or to one in which a non-eosinic dye is used. If there is eczematous sensitisation to some constituent, patch-testing may reveal the cause. One firm in the United States offers to supply doctors with patch-testing outfits of the constituents of its products. It has to be remembered that toothpastes may also cause cheilitis, or even an eczematous dermatitis.[3]

Nail varnish, when it causes trouble, usually does so where the hands come into habitual contact with the skin—e.g., on the eyelids, ears, and neck, and around the anogenital region. The hands themselves are rarely affected. Cuticle remover, another primary irritant, may affect the same sites as nail varnish, or it may be a cause of paronychia. It may also be responsible for brittleness and flaking of the nails, but the chief cause of this is the excessive degreasing and dehydrating action of modern detergents.

There are many interesting side-lines to the study of cosmetic dermatology; for example, dermatitis has been attributed to the use of nail lacquer as a coating for costume jewellery.[4] Nickel or chromium plating is most likely to be responsible when watch-straps, ear-clips, or other metallic articles are involved. Eczematous reactions of the nail bed have been reported from "under-coats" containing synthetic resins and rubbers, and experimental work suggests that such substances can pass directly through the nail plate,[5] [6] causing discoloration, subungual hæmorrhages, loosening of the nail, and paronychia. Eau-de-cologne applied behind the ears may cause the peculiar linear Berlocque pigmentary dermatitis, and in creams it is sometimes responsible for hyperpigmentation of the face. Other perfumes may be the cause of sensitisation dermatitis. It is as well to advise patients that the more expensive cosmetics are not necessarily the least likely to cause sensitisation, particularly where perfumes are concerned, for the most exotic preparations have had their victims. Cosmetic dermatitis is not confined to its users; Plotz[7] has described a dermatitis in infants caused by contact with their mothers' lacquered hair.

Among clothing, reactions are sometimes caused by dyed furs (the "para" group again), other dyed materials, nickel-plated fittings, and rubber articles such as dress protectors. Rubber sponges used for applying cosmetics, or for general purposes, have given trouble,[8] and so have the rubber fillers of eyelash curlers.[9] With rubber, it is the accelerators, activators, or anti-oxidants, usually synthetic organic compounds, that are responsible. One of them (an anti-oxidant—the monobenzyl ether of hydroquinone) may also cause depigmentation of the skin.[10] Synthetic plastic and adhesive materials used in the manufacture of hats and shoes can also cause dermatitis.

Hypersensitivity to cosmetics may be specific, and a true allergic phenomenon. Why then do individuals acquire hypersensitivity to cosmetics which they have used for years with impunity? Occasionally this may be due to some change in the composition of the cosmetic, but clinical experience suggests that it is often caused by a change in the health of the user. States of autonomic overexcitability seem to run parallel with an all-round increase of skin sensitivity. This clinical belief has recently been given some scientific backing by the demonstration of increased sensitivity of the skin of guineapigs to contact irritants applied after a period of interference with the animals' sleep.[11]

Dr. A. E. Gow, physician to St. Bartholomew's Hospital, London, died on Sept. 19. Dr. Gow was honorary physician to the household of the Duchess of Kent.

Sir Geoffrey Vickers, v.c., has been appointed a member of the Medical Research Council by the Privy Council. The following have also been appointed members after consultation with the M.R.C. and with the president of the Royal Society: Prof. G. R. Cameron, f.r.s., Prof. A. J. Lewis, and Sir James Spence.

THE OCCUPATIONAL ADAPTATION OF HIGH-GRADE MENTAL DEFECTIVES

J. Tizard
M.A. N.Z., B.Litt. Oxfd,
Ph.D. Lond.

N. O'Connor

Ph.D. Lond.

From the Medical Research Council Unit for Research in Occupational Adaptation

Mental-deficiency Hospitals

In England and Wales there are just over 105,000 mental defectives under statutory care. The Ministry of Health (1950) gave the number in institutions in January, 1949, as 54,887; the rest were [illegible] or statutory supervision. Of those in [illegible] were children under the age of 16; the remaining 47,000 were adults.

Every patient is *classified* according to the grade of his defect, but no figures are given by the Ministry, or by the Board of Control, as to the number of idiots, imbeciles, and feeble-minded persons in institutions. Nor is it easy to arrive at an estimate of the numbers in each grade.

From figures published by Penrose (1949) based on his Colchester survey, and from information given later in this paper, one of us (Tizard 1951) has calculated that about 54% of adult patients are above imbecile grade in intelligence. If *Penrose's data are representative, two-thirds of the feeble-minded or dull patients in institutions are young persons between 16 and 29 years of age; while only 3% of adults in* institutions are more than 45 years of age and above imbecile grade in intelligence.

Thus it seems probable that over half the adult cases in institutions are high-grade patients; and of these a large proportion must be regarded as young, trainable adults and adolescents who may eventually be discharged from the provisions of the Mental Deficiency Acts.

EXISTING TRAINING METHODS

The occupational potentialities of high-grade and low-grade patients are very different. Low-grade patients need, and are given, occupational therapy. High-grade patients on the other hand, need occupational training, and are today employed either on work which is of direct use to the hospital, or on skilled or semi-skilled trades under the *direction of craftsmen. For this work they* receive small sums in pocket-money. Patients on daily or resident licence usually work on farms or as general labourers, or go to small firms as errand boys, to public houses, to laundries, to hospitals as domestics, or to private employers as servants. These patients receive larger sums as pocket-money, and usually have the rest of their money, except for that deducted for board and lodging, banked for them. They are able to draw on their bank account for clothes, holidays, presents, and so on, with the permission of the hospital authorities. In 1946 there were 5571 patients on licence from institutions in England and Wales; and an average of about 900 patients is discharged annually.

During the last few years the number of patients on daily and resident licence has increased considerably. Training schemes in institutions have, on the other hand, changed little. Numbers of patients work as labourers in mental-deficiency hospitals, and this training probably stands them in good stead if they later work as labourers *in the community. Large numbers of high-grade patients* can, however, still be found working at the occupations *described by Bickmore* (1913): carpentry, bookbinding, envelope-making, box-making, brush-making, basket-making, raffia work, mat-making, tin-smithing, tailoring, upholstering and mattress-making, printing, needlework, painting, building, wood-chopping and bundling, and shoe-repairing. The titles of some of these occupations *give little idea of the character of the work performed;* and the teaching methods of the trainers, and the equipment used in the workshops, are often extremely old-fashioned. Only in the protected *environment* of a hospital could these uneconomical and out-moded methods *continue.*

The following specific criticisms of much of the *occupational training may be made:*

1. *Most of the training is designed to give the patients* something to do rather than to employ them on work of value to the community. In times of severe and chronic unemployment, when very few defectives can be sent on licence to the community, and when public policy deems it expedient for institutions not to compete in any sense with private employers, this is readily understandable. In times of full employment *and general shortages a different attitude to the training of defectives seems advisable.*
2. The work done in institution workshops bears almost no relation to the types of job which defectives do when on licence. A mere handful of those who are trained so laboriously on the skilled and semi-skilled operations learn to perform them competently enough to be able to obtain work as artisans in the community. The bulk of defectives are employed only on less skilled work.
3. The equipment used in institution workshops is almost without exception obsolete as far as industry is concerned. Much work which is done commercially by machine is done by hand, or for the most part by the most primitive of machines. Little is done to speed up production to the tempo required to keep a job in the community, and the defectives get no experience in handling machines, and so becoming accustomed to them. Consequently output remains low, and even though labour is free the selling costs are often higher than commercial selling costs, which are reduced by the economies of large-scale buying and by efficient machine production. This factor of economic cost is obscured in the annual reports of some institutions which give "turnover figures" but not a profit-and-loss balance-sheet of workshop expenses.
4. Little contact is made with commercial firms which might be induced to take numbers of defectives who have already received some training into their own factories. Thus, in many hospitals, a potential stepping-stone to life in the community is not made use of.
5. The work is too often carried out in an atmosphere devoid of incentives. Neither the report of the Mental Deficiency Committee (Wood Report 1929), nor *Bickmore* (1913) mention monetary rewards—*assuming apparently that* praise and blame from an instructor are sufficient for defectives. But the absence of monetary rewards in some hospitals makes the problem of providing incentives a *difficult one*, and also prevents patients from learning the value of money. Unless those who will probably be sent on licence in the future *are given more money to spend while they are in institutions, they are unlikely to learn from their own mistakes how money* can be wasted, and what money can buy.
6. *The supervision of patients on daily service* or resident licence is often inadequate. [illegible] *no social worker, and few* [illegible] *hospitals nurses do the necessary work, but in any case few hospitals have more than one or two people who are responsible* for placing and follow-up. For adequate supervision a much greater number is needed.

COST OF PRESENT METHODS

The economic cost to the community of the present methods of employing *defectives has been critically examined by Gibbens (1948).* He analyses the statistics of the Surrey County Council for *1938 and concludes that* some 67% of institutional defectives are apparently regarded as being employable in the full sense. The London County Council statistics, also analysed by Gibbens, suggest that about 43% of patients are fully employable. From these two figures he concludes that fully 40-50% of adult institutional patients are employable.

Other work on the employability of defectives, which *we have reviewed elsewhere (Tizard and O'Connor 1950),* emphasises that the number of defectives capable of *satisfactory social and occupational* adjustment in the community has often been seriously underestimated.

Economic conditions have been largely responsible for this; but under conditions of full employment there is still a considerable lag in the sending of patients to licence.

The number of patients rehabilitated today could be greatly increased if ways could be found of lessening the high incidence of occupational maladjustment among defectives sent on licence to the community. The extent of this maladjustment is indicated by the large numbers of licences revoked each year in most hospitals for mental defectives. One of its consequences is that many physician-superintendents are reluctant to send patients on licence because of the probabilities of failure, with its resulting economic, social, and personal costs. Unfortunately, however, keeping patients in institutions also entails economic, social, and personal costs, which are no less real because they are not counted or measured.

SIZE OF INSTITUTIONS

Difficulties in training high-grade patients are increased by the fact that most institutional defectives are housed in huge "colonies" of 500–2000 or more beds. In 1946, according to an analysis one of us (Tizard 1952) made of information published by the Board of Control (1931, 1946a and b), more than two-thirds of all defective patients were in institutions of more than 500 beds, while nearly half were in institutions containing more than 1000 beds. Though the need for smaller units has long been recognised, in 1946 only 13 institutions had hostel accommodation for patients. The comprehensive colony is believed to be the most economical method of housing institutional patients. Thus the Wood Report (1929) argues that in comprehensive colonies high-grade patients can be employed on maintenance and essential services, so saving the cost of paid staff. Nevertheless separate hostels for high-grade patients appear to be psychologically desirable; and, as the figures given below indicate, patients in them could contribute substantially to their keep. On balance, classified institutions might be both more economical as well as more in keeping with current psychiatric opinion than comprehensive ones.

Employability of High-grade Defectives

The widely recognised shortcomings of the mental-deficiency services, which have been sketched above, formed a starting-point for the research which has been carried out during the last three years, under the direction of Prof. Aubrey Lewis. The purpose of the research has been to study the conditions under which institutional high-grade defectives can best be employed, both inside and outside institutions. This has meant some study of the competence of high-grade patients, and an investigation into behaviour problems. Experimental workshops have been set up in Darenth Park, in collaboration with Dr. J. K. Collier Laing, the physician-superintendent, and his staff. Darenth Park is a hospital in the South-East Metropolitan Region which includes among its patients several hundred high-grade, adult defectives. Here patients have been trained for jobs to which they might later be sent from the hospital to perform in normal industrial conditions. Some consideration has been given to problems of supervision and incentives in the training workshops. The bulk of the research has been carried out with male patients.

We group our results under four main headings: psychometric studies of high-grade male defectives and prediction of occupational success; workshop investigations; success of workshop patients on daily licence; and factors influencing the success and failure of other patients on daily licence.

PSYCHOMETRIC STUDIES

In 1949 a psychometric study was made of 104 cases.

The sample consisted of all those male patients admitted consecutively to Darenth Park over the preceding three years who were feeble-minded, not grossly handicapped physically, still living and working inside the institution at the time of testing, and between 16 and 45 years of age. They were given a battery of intelligence, psychomotor, and personality tests, and with the help of Dr. J. M. Crawford we also rated them for instability and anxiety.

In 1950 a second sample of 100 patients was given the most promising of the tests in the 1949 battery, together with additional tests included for research purposes. In the second sample half were fresh cases; the remainder had already been tested in our first study. It was possible with this combination of data to check Beta weights and obtain test reliabilities.

Results can conveniently be discussed under the headings of intelligence tests, other cognitive and motor tests, and objective tests of personality.

Intelligence Tests

Perhaps the most significant finding was the high average intelligence quotient (I.Q.) and the wide range of scores obtained by patients on standardised tests of intelligence. Combining results with the Progressive Matrices test, obtained by us at Darenth and another hospital, and by Stickland (1952) at a third hospital, we find the mean I.Q. of 360 adult patients to be 75·61 (S.D. 10·01). Stickland reports no significant difference between the scores of males and females, so it seems likely that these figures are representative for both sexes.

A suggestion sometimes made that the Matrices test is unreliable for defectives has not been confirmed by our experience of retests after long periods.

Other Cognitive and Motor Tests

Inadequate standardisation of these tests makes it difficult to compare our findings with those of other investigators working with normal adults. Since they have been fully discussed elsewhere (Tizard 1950) the technical difficulties of interpreting results are omitted. One finding from Darenth Park should, however, be mentioned. The median reading-age of 100 patients tested on the Schonell mechanical reading scale, which has been very soundly standardised on Army recruits, (Ministry of Education 1950) was 8·6 years; and the range of reading ability was wide, being as follows:

Score (to nearest year) ..	14	13	12	11	10	9	8	7	6	5 or less
No. of cases..	2	3	5	12	16	14	16	8	4	20

100

The correlation between reading-age and verbal intelligence, as measured on the Bellevue verbal scale, was only 0·427. This finding suggests, first, that many patients in hospitals for mental defectives are educationally retarded—that is, they are more backward educationally than they are in intelligence, and hence might profit by further schooling—and secondly, that a very considerable proportion of them are capable of reading simple material, and that adequate provision of suitable books and other reading matter is desirable. Some hospitals would like to do more to teach patients but have difficulty in obtaining the necessary funds to appoint teachers.

Objective Personality Tests

It has been held that one aspect of neurotic personality is the poor work-history of the neurotic; and an attempt was made to test this hypothesis with a defective population. We also studied the relative value, for predicting success at work, of tests assessing neurosis, the diagnosis of a psychiatrist, and a quantified history of behaviour. Success was measured in terms of the number of failures of a particular boy to hold jobs. A full analysis of results is given elsewhere (O'Connor 1951a and b, 1952). The main findings confirmed the view that the outlook for success at work was best measured, not by cognitive or intelligence tests, but by tests of personality traits. This conclusion was reached by separate analyses of the results with both the first and second samples. Further studies, of which details may be had on request, made it clear that the use of tests for predicting whether or not a patient should be given a trial on daily licence is of doubtful value; and, in view of this, all patients (other than those who are manifestly unable to work in the community) should be given opportunities for daily licence from time to time, as is already done in some hospitals. The important problems of occupational psychiatry among the mentally handicapped are not problems of selection, or even of vocational guidance as the term is usually used today: rather they are problems of training patients, if necessary in a sheltered environment, and of providing adequate supervision and assistance in the community. Occupational training in the wide sense of the word must include the training and habilitation of those unstable patients who constitute the chief sources of trouble both to their families and to the community. One such training scheme has been described by Laing (1951).

WORKSHOP INVESTIGATIONS

In January, 1950, the Darenth and Stone Hospital Management Committee set up a first, and subsequently a second and third, experimental workshop. These were to serve two purposes: (1) to learn whether it is possible to train defectives to do such routine repetitive work as is done by normal workers in industry, and whether their training in institution workshops contributed to their success; and (2) to determine the optimum conditions of employment.

Suitable work of a routine repetitive nature, paid for at trade-union piece-rates, was obtained from two firms willing to subcontract work to Darenth Park. The firms were approached through the Ministry of Labour.

One firm sends plastic for hand trimming, and one sends cardboard for folding and processing. Initially small quantities of this unskilled work were sent, but after a few weeks the firms sent much larger quantities. At present 140 patients are employed in the shops.

The experimental shops are controlled by hospital nurses. For each boy daily and weekly records of output are kept, and the boy is paid according to what he earns. All money received from the firm is credited to the patients, and at first they were allowed to receive in cash half of what they earned, up to a maximum of about £1. The rest was banked for them, and they were encouraged to save as much as possible to buy clothes, presents for relatives, and pay for holidays and outings and so on.

During 1951, however, this system was modified by the hospital authorities for administrative reasons, and the incentive bonuses were scaled down.

The average wage is now 6*s*. 8*d*. a week, the range being 2*s*. 6*d*. to 15*s*. with 2*s*. 6*d*. bonus for the best boys in each shop. Outings are still arranged and boys who begin work on licence are fitted out with clothes, half the cost of which is met directly out of their earnings. The number of lower-grade patients has also been increased; so the original function of the shops as training centres has been modified.

Between the beginning of May and the end of July, 1950 (i.e., before the system was modified), the average weekly wage of 24 boys employed was just over 27*s*. The shops as a whole earned £1250 during the first eight months, and £2750 in just over a year. During 1951, £3000 was earned by the shops as a whole. The patients work a $35^1/_2$-hour week to fit in with hospital requirements.

An experiment was designed to determine the effects of different types of supervision on the behaviour of patients in the shops.

Three groups of 12 patients each, matched for previous productivity, served as subjects. The mean I.Q. of the patients taking part in the experiment was 68·00 (S.D. 9·57 points) on the *Bellevue verbal scale*. The mean age was 19·45 years (S.D. 4·41 years). Three types of supervision—strict, friendly, and laissez-faire—were carried out by three nurses who acted as supervisors during the investigation. The experiment ran for 12 weeks and was divided into three periods of 4 weeks each, so that each supervisor served in each of the three shops, changing his type of supervision in each. Behaviour and output during the experiment were recorded quantitatively for each boy, and the results analysed by analysis of variance (Tizard 1952).

Two findings may be mentioned:

1. Significant differences between the behaviour of groups under the three kinds of supervision were noted. Laissez-faire supervision gave rise to considerable aggression, which was not found in groups under strict or friendly supervision, either in or out of the workshops.

2. The experience obtained suggested ways in which nurses might be more efficiently trained to undertake supervision. Both practical training, such as is given to teachers in training, and formal discussions of what to do in handling patients (on lines adapted by the Hawthorne investigators) seem desirable.

SUCCESS ON DAILY LICENCE

During 1950 and 1951 a total of 194 patients were employed in the workshops, of whom 60 were tried on licence. Some of the patients went from the workshops to work at one of the firms subcontracting work (Kolster-Brandes of Sidcup). Others went to other work for which they had had no special training. In December, 1951, their distribution was as follows:

From workshops to daily licence and succeeded on their first trial	[illegible]
From workshops to daily licence and succeeded after being unsuccessfully placed	5
Tried unsuccessfully on daily licence	15
Dismissed or removed from workshops (not tried on daily licence)	[illegible]
From workshops to resident licence with their parents ..	[illegible]
In workshops but not tried on licence	[illegible]
Total	194

The table shows the success and failure of patients tried on licence at Kolster-Brandes (K.B.) and at other types of employment. Though the numbers are not large, there is a significant difference between the success of boys placed with K.B. as compared with that of boys placed elsewhere. This is believed to be due not only to the training received but also to the type of supervision given at a large firm where patients are under the charge of an exceptionally capable and understanding supervisor. We are unable to determine the extent to which each of these factors contributed to the boys' success on licence, but there is no doubt about the success itself. The boys seem to benefit both by working alongside normal employees and by remaining in company with others whom they know.

OTHER PATIENTS ON DAILY LICENCE

In addition to the boys who went to a factory from the hospital workshops, many were employed directly, without training, as building labourers. Apart from physical disability three main causes for failure can be seen from an analysis of the job records. These are lack of motivation, failure due to initial lack of adjustment to the job, and finally emotional instability amounting to neurosis.

Examples of apparent changes in motivation were first seen in the workshop, when boys who had been working at a slow tempo speeded up almost overnight. Similar changes were reported from supervisors on the jobs to which the boys were sent. A major and remediable cause of failure was initial maladjustment. This was particularly noticed among the boys working on the building site. On this job supervision generally

SUCCESSES AND FAILURES AS BETWEEN K.B. AND OTHER FORMS OF DAILY LICENCE (EXCLUDING 2 BOYS TRIED BOTH AT K.B. AND IN OTHER FORMS OF EMPLOYMENT)

—	Daily licence			
	Successes	Failures	Total	Percentage failure
K.B. ..	27	6	33	18
Other ..	14	11	25	44
Total ..	41	17	58	

$\chi^2 = 4{\cdot}58$. $p < {\cdot}05$.

was not good; gangers under pressure to complete contracted work showing little patience with boys who had never attempted heavy work under competitive conditions. In the first month 34% of defectives left as compared with 21% of normal labourers; but over the first six months the percentages were nearly the same—51% for the defectives and 58% for other workers. Emotional instability or neurotic tendency was responsible for some failures. Failures of this latter kind were usually for disciplinary reasons and the boys were often of above average intelligence for the group. Histories usually supported test findings and psychiatrists' opinions of the instability of these boys.

Emotionally unstable boys are in a minority; and we feel that much failure can be avoided, either by suitable supervision, or by adequate motivation and wise guidance. Such a policy at Darenth Park has given the following results:

In April, 1949, 65 of a total of 1015 male patients were on daily licence, but by March, 1951, 161 of the 1087 male patients were working outside the hospital on licence—an increase from 5·4 to 14·8% in two years, without an appreciable increase in the incidence of failure. During 1951 patients on licence earned £30,000 and paid £16,500 to the Treasury for their board and lodging. No comparable increase has occurred in the country as a whole.

Summary

Some 55,000 mental defectives, of whom about 47,000 are adults, are in mental-deficiency hospitals or institutions in England and Wales. Half of these are feebleminded.

The training of these people is often not related to work which they might be called upon to perform when sent on licence, because, with very few exceptions, institutional policy has not been to return defectives to the community, but to segregate them. Hence training tends to be misdirected from this point of view, incentives are unreal and ineffective, and training costs are unnecessarily high.

In our view large institutions are unsatisfactory as places for training.

High-grade defectives trained for and employed on simple repetitive work can, and do, succeed in many cases, when well supervised and adjusted to strange surroundings. Few fail, and of those who do many can be rehabilitated when attention is given to their problems.

Psychometric cross-sectional studies and a longitudinal workshop experiment are reported. With high-grade adolescent defectives with a mean I.Q. of 70–75, tests of neurotic tendency better predict success at work than do tests of intelligence. In general, however, with prediction at its present level, no practical use can be made of these findings; selection for jobs in a period of full employment should be as liberal as medical opinion and social safety will allow.

Training and supervision are apparently more important than considerations of basic "psychological" quality, whether of abilities or personality traits. The main problem of occupational psychology is not selection, but training, motivation, and supervision.

Our thanks are due to Dr. J. K. Collier Laing, physician-superintendent of Darenth Park, for the facilities which he and his committee have generously placed at our disposal, and for his interest in the work.

SUPPLY OF NURSES

SPEAKING at Plymouth last week, Mr. Iain Macleod, the Minister of Health, said that during the four years since the inception of the National Health Service the total nursing and midwifery staff in hospitals had increased by about 25,000 full-time and 9000 part-time, and over 30,000 additional hospital beds had been opened, while the number of student nurses (51,648 at the end of June) was the highest yet recorded. While this progress gave some cause for satisfaction, three considerations must be kept in mind.

> "First, there are still some fields, notably our mental hospitals and mental-deficiency institutions, in which there is a really grave shortage of nurses. Secondly, the pressure of work in many of our acute wards is tending to increase because of the introduction of complex new techniques and the earlier discharge of patients. Thirdly—and this is perhaps the most fundamental consideration—we cannot expect the numbers in the profession to continue increasing indefinitely: not only is the total number of young women now considerably smaller than just before the war because of the low birth-rate in the '30s, but the number of competing professions open to them is tending all the time to increase."

It was essential, the Minister said, to make the best use of all the nurses. Among ways of doing this were the effective use of the preventive health services, including the health visitor and home nurse, and a reduction of the incidence of wastage during nurse-training. About 20,000 student nurses were admitted to training schools each year, yet the annual output of trained nurses was only about 9000–10,000. It was hoped that the Hospital Job Analysis conducted by the Nuffield Provincial Hospitals Trust, the report of which was expected soon, would give useful guidance towards making a better planned use of trained nurses and ancillaries.

> "When there is, as here, a strict upper limit to the number of people with particular qualifications, it is merely elementary common sense to make sure that they are employed only on work calling for that qualification and that other work is devolved to less highly qualified staff. It also becomes a public duty to make sure that the number of qualified people employed is the minimum needed for the work to be done. In other words, that there is neither waste nor extravagance."

Mr. Macleod also referred to the three-year gap from 15 to 18—the minimum school-leaving age and the minimum age at which training as a nurse can now begin. No problem arose if the girl was able to remain at school until the age of 18, but the total numbers required by the profession were such that they could not all be recruited from that source; and the problem was how to maintain an interest in nursing among a sufficient number of those girls who have to leave school and take a job at 15 or 16. After speaking of "pre-nursing courses," cadet schemes, and the certificate of the National Nursery Examination Board, he pointed out that the girl who takes another job is by no means irrevocably lost to nursing: a survey by the Nursing Recruitment Centre showed that no fewer than 34·8% of the candidates accepted as student nurses during a three-month period had come from other work, while a further 10·5% had come from nursery work or training.

> "I am very conscious," he added, "that the problems of the teaching hospitals in this field of nursing recruitment are a good deal simpler than those of the ordinary hospitals, and the ordinary hospitals are after all the great majority. We must watch carefully to see that we do not lose the ground we have gained."

INTERNATIONAL CONGRESS OF INTERNAL MEDICINE

In 1947 the Royal College of Physicians arranged an International Congress of Physicians which was held in London. This gave rise to the formation of the International Society of Internal Medicine, which had its first congress in Paris in 1950. The second congress met in London last week, from Sept. 15 to 18, under the patronage of Her Majesty THE QUEEN and the presidency of Sir RUSSELL BRAIN, P.R.C.P. At the opening session the guests were welcomed by Mr. IAIN MACLEOD, the Minister of Health, and a Government reception was held on the same evening at Church-House, Westminster. On the next night there was a reception at the Royal College of Physicians, and on Sept. 17 the congress dinner took place at the Mansion House.

Speaking at the dinner, Lord MORAN said that no visit to London was complete unless the visitor dined with the Lord Mayor. In England we revered tradition, and when tradition was lost in time the reverence was touched with affection. The City of London was old yet ever young, and it was not without significance that the present Lord Mayor, Sir Leslie Boyce, was born and bred in Australia. Responding, the LORD MAYOR claimed that London was still going strong, even if once in a thousand years it had to send to the other end of the world to find a Lord Mayor. On the assumption that internal medicine was something out of a bottle, he had been apprehensive lest the congress members would convert his Egyptian Hall into a giant dispensary; but he was reassured on learning that the business of the congress consisted in symposia, defined by the dictionary as drinking parties. He hoped that the delegates would take back the greetings of the citizens of London to the civic heads of the cities whence they came. Prof. A. GIGON, of Basle, proposing the toast of Internal Medicine, considered several possible new specific names for the genus *Homo*, and (adopting that of Bergson) concluded that London showed him both *sapiens* and *ridens*. Medicine, and the organisation of medical congresses, needed both the mosaics of team-work and the obelisks of individuality, and he thanked those whose long labours had combined to create the *jardin d'amitié* of the past few days—including particularly Lady Brain and Sir Harold Boldero. *Vivat, floreat, crescat* Internal Medicine! Sir RUSSELL BRAIN, in his reply, paid tribute to the two assistant secretaries, Dr. Alastair Hunter and Dr. J. F. Stokes, and their chief Sir Harold Boldero: "as a centre of coördination he far surpasses the cerebellum." The physician of today must always be anxious as to whether he has left out any of those investigations that may be crucial in diagnosis. Was there, then, any hope of internal medicine becoming simpler? He believed not. As more facts accumulated, there must be far more relations between them. Only ignorance was simple. Now that knowledge could no longer be brought into one mind, we must bring minds together. Having reached (according to biologists) the limit of evolution of the human brain, we must evolve in another direction—beyond *Homo sapiens* to another stage. For this he suggested the name *Homo consultans* (a term which expressed the highest activity of the human mind). Man must somehow become wise enough to develop in every sphere of life the art and technique of consultation.

The scientific sessions, held at Friends House, took the form of four symposia, with subsequent discussions.

THE SPRUE SYNDROME

The first scientific meeting of the congress was held under the chairmanship of Dr. NANNA SVARTZ (Stockholm).

STEATORRHŒA OR IDIOPATHIC FATTY DIARRHŒA

Dr. C. D. DE LANGEN (Utrecht) spoke of his clinical experience with tropical sprue in Batavia. He laid stress on the need to look on sprue as a disease that affected the whole man and not merely as a disturbance of digestion. Steatorrhœa of varying duration and severity might be associated with many conditions—with Graves's disease, Addison's disease, cardiac failure, Whipple's disease, or even the smoking of a Havana cigar. One of the most constant features of the disease was meteorism, and he did not believe that this was caused by an abnormal degree of gas formation due to fermentation processes in the small intestine; on the contrary, he attributed it to defective absorption of gas, this defect being caused by a disorder of circulation. In Dr. de Langen's opinion, the only people who developed sprue were those with an unstable peripheral circulation, and the circulatory disturbance was the basis of the general absorption defect. He denied that conditions in the capillary bed were entirely controlled by hydrostatic and osmotic pressure, and pointed out that every part of the body, including the intestinal wall, had a capillary system with special characteristics: conditions in the capillary bed varied not only from tissue to tissue but also from moment to moment in the same tissue. He agreed with many of Verzár's observations, but thought they could be interpreted better in terms of circulatory defects than in terms of a disturbance of phosphorylation. The assumption of a circulatory defect also explained the absence of morphological changes in the intestinal wall. Substances such as folic acid and strychnine, which improved absorption, did so by virtue of their effect on the circulation. Metabolites were taken up not only by the villi but also by the capillaries of the intestinal wall. Thus absorption became a diphasic process analogous to the diphasic excretion process of the kidney. Normally, the comparatively long fatty-acid molecules would "bounce" up and down on the outside of the capillary wall and would find it easy to penetrate head-on when the circulation was active and the "pores" were dilated. They would find their penetration inhibited by a defective circulation and thus their absorption would be impaired.

BLOOD CHANGES AND VITAMIN DEFICIENCY

Dr. A. L. FROEHLICH (Antwerp) began by discussing the blood levels of the minerals in idiopathic steatorrhœa. The values for both sodium and chloride were diminished, especially if there was much fluid loss. The potassium level usually remained unchanged but might drop occasionally with the disappearance of œdema. As deoxycortone administration did not improve these biochemical findings, they were not due to cortical deficiency of the adrenal. A drop in the calcium level with the appearance of tetany was common. This Dr. Froehlich attributed rather to a primary absorption defect than to the formation of calcium soaps, for it responded rapidly to injections of vitamin D. The serum-protein level was also reduced, mainly through reduction of the albumin fraction; the reason for this was either the abnormal use of amino-acids for energy purposes or, possibly, defective synthesis in the liver. The level rose with cortisone therapy. Total lipids were reduced. The free-cholesterol level remained normal, as did the neutral fat, whereas the esterified cholesterol was reduced. A similar picture occurred in malnutrition and pernicious anæmia. Dr. Froehlich thought that vitamin B_{12} might be necessary for cholesterol and phospholipid formation in the liver, for there was a rapid rise in the levels with the administration of this vitamin in cases of pernicious anæmia.

He went on to discuss the results of feeding experiments. The blood-sugar did not respond in the usual way to the ingestion of glucose. The curve remained flat, and in due course even hypoglycæmia might develop. Although he agreed with Frazer's theory of a mechanical bsorption defect, he did not regard it as a sufficient xplanation of the phenomenon of hypoglycæmia. An bnormal avidity for glucose by the liver in idiopathic teatorrhœa might be the basis for this reaction. Reviewng the different opinions about the response of blood-fat o a fat meal, he associated himself with those workers who found an absence of the normal postprandial hyperipæmia, mainly due to the absence of an increase of neutral fat. As far as the bile was concerned he found n absence of choline and bile salts in steatorrhœa, which he tentatively put down to liver failure. He disagreed with Ingelfinger and Moss's hypothesis of defective acetylcholine synthesis in the intestinal wall. These authors found no response to neostigmine injections in cases that showed a radiological "deficiency-pattern" of the small intestine, but found a prompt response after the administration of acetyl β-methylcholine. Dr. Froehlich, on the other hand, found in such cases that neostigmine markedly increased segmentation. Deficiency of vitamin B was a common finding, mainly in the tropical variety of the disease, and these changes could be satisfactorily explained by Frazer's competition theory. The macrocytic anæmia might be due either to a lack of intrinsic factor or to the poor absorption of the extrinsic one. Deficiency of the fat-soluble vitamins was common—mainly of vitamin D with associated osteoporosis and tetany. Hypoprothrombinæmia was not an unusual finding, though gross hæmorrhages were rare. Dr. Froehlich described one case of abnormal pigment formation in smooth muscle, very similar to the findings in experimental vitamin-E deficiency.

He believed in the essential difference between idiopathic steatorrhœa and tropical sprue. A third syndrome—the bile-lack syndrome—might have to be separated from the others.

ÆTIOLOGY OF IDIOPATHIC STEATORRHŒA AND RELATED CONDITIONS

Prof. A. C. **FRAZER** (Birmingham) then outlined his conception of the sprue syndrome. Neither the liver nor the adrenal could be looked upon as the organ primarily responsible for idiopathic steatorrhœa, for neither with gross liver damage nor in Addison's disease did anything resembling sprue syndrome occur. The primary fault lay in the intestine.

Fat-balance studies and experiments with the intraduodenal administration of glucose and even urea had shown that the absorption not only of fat, but also of substances which depend for their absorption on different mechanisms, was defective. The ubiquitous nature of the defect suggested that the cause was purely mechanical. Radiological studies had confirmed this opinion. The "deficiency pattern" which was a constant feature of idiopathic steatorrhœa could be reproduced in the normal individual by the administration of various mucigenic substances. The admixture of increasing quantities of mucus to an ordinary barium suspension in vitro would produce an increasing degree of flocculation. If non-flocculable barium was used for the radiography of the small intestine, the "deficiency pattern" would disappear. These facts suggested that the "deficiency pattern" was not due to incoördination of the intestinal musculature caused by vitamin deficiency, but to flocculation of the barium by excessive mucus. When non-flocculable barium was used, the radiological appearance of the small intestine was that of a dilated gut with reduced motility. Frazer regarded this reduced motility—probably involving the villi—and the barrier created by excessive mucus secretion as two important factors depressing and delaying absorption from the small intestine.

Wheat-flour played an important part in the pathogenesis of cœliac disease, for such children were cured if it was removed from the diet. On such a diet they differed from normal children only in so far as their abnormal sensitivity to wheat-flour remained. They would deteriorate again if wheat-flour was once more incorporated in the diet. The mechanism appeared not to be an allergic one. Intestinal motility was depressed and not stimulated; there was no eosinophilia; and skin tests with wheat-flour were negative. It could be shown that the agenising process was not responsible, for substitution of non-agenised for agenised flour did not affect the results. It was the gluten portion which was the essential factor. This was not a mucigenic stimulus, but interfered with intestinal motility. Frazer therefore believed that in cœliac disease depressed motility played a more important part than excessive mucus formation.

Delayed absorption led to the following secondary effects: in the first place the caloric intake and the intake of essential nutrients might be reduced and cause emaciation, especially if further aggravated by a deficient appetite. Secondly, owing to the prolonged presence of a rich medium in the small intestine, there was an extension of bacterial growth into regions which were normally almost sterile. This change in the intestinal flora caused fermentation of carbohydrates, with the production of short-chain fatty acids which stimulated mucus secretion. Frazer, however, agreed with de Langen that this was probably not the only cause of meteorism. Abnormal bacterial acitivity might lead to the formation of amines that could affect gastro-intestinal motility and possibly have an effect on the vessels of the small intestine.

The degree and extension of bacterial growth would determine the degree and severity of the disease. If it was slight, a mild "pre-sprue" condition would be created; with further extension a vicious circle was set up and there would be an overt sprue syndrome.

Primary precipitating causes of the disease were mucigenic stimuli. Infection, infestation, and the ingestion of rancid fats probably played important parts.

EFFECT OF CORTICOSTEROIDS

Dr. **CHESTER JONES** (Boston) started his communication by objecting to the term "idiopathic steatorrhœa," because, he said, this seemed to imply that the only feature of the disease was a disturbance of fat absorption. Absorption of many other substances was also defective, and he therefore preferred the non-committal term "sprue syndrome." The tropical variety responded so readily to liver extract, folic acid, and vitamin B_{12} that it was regarded by many as a deficiency disease. Dr. Chester Jones suspected that the two diseases had a common denominator, but did not regard their identity as proved.

He went on to discuss clinical, biochemical, and therapeutic findings in a series of 9 cases of non-tropical sprue from his own clinic. All showed marked clinical, radiological, hæmatological, and biochemical changes. The biochemical changes included depressed glucose and vitamin-A tolerance tests. The latter test and the presence of steatorrhœa he regarded as the most constant features of the disease. All cases had responded poorly to the usual form of therapy, and, after a control period, treatment with cortisone or A.C.T.H. was started. (Dr. Chester Jones made it clear that it was the well-known effect of these substances on cellular activity that had induced him to start this treatment, and that it should not be regarded as a form of replacement therapy.) All patients showed marked improvement after a latent period of a few days. There was a feeling of well-being, the stools diminished in number, and meteorism disappeared. Fat-balance studies revealed a reduction in the percentage of dietary fat excreted: the response of the chylomicron count after a fatty meal improved, and so did the glucose-tolerance curve. The serum-protein level rose. Hæmoglobin values responded slowly, and the vitamin-A tolerance showed little change. With cessation of therapy patients deteriorated again. One patient did not respond to the original course of treatment, but improved when the dose was raised.

Dr. Chester Jones thought that the essential feature of the disease was a general absorption defect due to a "disturbance in intestinal mucosal cell dynamics."

DISCUSSION

Dr. F. Bulic reported on an epidemic of steatorrhœa in the Yugoslav army during the late war. The men were on a deficient diet which consisted mainly of meat and small amounts of cornflour. Many developed a frothy diarrhœa, and the clinical appearance resembled the dry form of the famine syndrome. The addition of tinned food to the diet did not lead to improvement. The epidemic, however, was cut short when the company was moved to a different district, where fresh fruit and vegetables were available.

Dr. H. A. Salvesen (Oslo) discussed the incidence of low blood-pressure in idiopathic steatorrhœa. Hypertension, he said, did not occur, and there was a tendency to hypotension. No correlation between the blood-pressure findings and the presence of anæmia or electrolyte changes could be established. The cause was not known, but Dr. Salvesen assumed that it was due to the lack of absorption of a pressor factor, possibly caused by defective fat absorption. Hepatitis with jaundice also reduced the blood-pressure, and tying of the common bile-duct in Goldberger dogs prevented experimental hypertension, possibly owing to liver damage. The responsible factor was assumed to be of lipoid nature.

Dr. A. Vaz Serra (Portugal) spoke of the poor results of treatment along orthodox lines and advocated intensive study of such possible ætiological factors as food and infection.

Dr. W. T. Cooke (Birmingham) discussed the correlation of various constituents of the fæces in steatorrhœa. He had found a significant correlation between total solids and fat, but not between water content and fat. A significant correlation existed between fæcal water content and sodium and in some patients also between water and potassium.

Prof. C. Jiménez-Diaz (Madrid) stressed the importance of the active secretion of fat into the intestinal lumen, as opposed to the defective absorption of dietary fat. He gave details of such excretion into isolated intestinal loops in dogs. Calorimetric studies revealed a correlation between fæcal fat content and total caloric excretion.

Dr. R. H. Girdwood (Edinburgh) made some interesting observations on the fate of the antimegaloblastic principles. Both in tropical sprue and idiopathic steatorrhœa he had found poor absorption of folic acid, and he therefore favoured parenteral as well as oral medication. One of his patients did not respond to prolonged and intensive folic acid treatment, but improved rapidly when he had penicillin injections in addition. After oral medication the citrovorum factor appeared as such in the blood and urine of patients suffering from pernicious anæmia. In cases of steatorrhœa with normal hydrochloric acid it was broken down and appeared as folic acid.

Dr. D. Adlersberg (New York) expressed his bewilderment at the multiplicity of theories about the pathogenesis of the sprue syndrome. He reported the response of a number of cases, previously resistant to treatment, to the administration of cortisone, A.C.T.H., and Compound F. It was necessary to start with an adequate dose, to avoid reducing this too soon, and to carry on with maintenance treatment indefinitely. He regarded intestinal obstruction as a not infrequent fatal termination of the disease.

Prof. E. Martin (Geneva) discussed the different manifestations of sprue and the need to elucidate the reasons for these differences.

Prof. C. Holten (Denmark) described a case of steatorrhœa and tetany due to a non-malignant growth involving the mesentery.

Most speakers seemed to agree that the absorptive defect is a general one which makes it unlikely that interference with such specific processes as the phosphorylation mechanism is concerned. The ubiquitous nature of the defect, and the absence of morphological changes, suggest a mechanical cause. Excessive mucus secretion, depressed motility, and depressed circulation were put forward as possible explanations. It was generally assumed that the intestine itself was at fault. Vitamin deficiencies were on the whole looked upon as of a secondary nature. An adrenal defect does not seem to be a primary cause, and treatment with corticosteroids is not to be regarded as replacement therapy.

The most important advances on the therapeutic side appear to be the withholding of wheat-flour from the *diet of children with cœliac disease,*[1] and treatment with A.C.T.H. or corticosteroids in adults with severe and otherwise intractable steatorrhœa.

DISTURBANCES OF FLUID AND ELECTROLYTE BALANCE

First Session

The proceedings were opened formally by Prof. Gigon, president of the International Society of Internal Medicine.

HOMŒOSTATIC MECHANISMS

Prof. J. G. G. Borst (Amsterdam) said that many years' study of the kidney had convinced him that it was endowed with intelligence; but it was also a member of a team—in fact of several teams. Most changes in body-fluids could be interpreted in terms of three types of natural diuresis which he had previously described.[2] These three types were water diuresis, saline diuresis, and the diurnal rhythm of water and salt excretion; each type of polyuria had a corresponding type of oliguria. But for the second mechanism (saline diuresis) it would be highly dangerous for normal people to eat soup, and in fact we should all have to go on a low-salt diet. This second mechanism was predominantly affected when cardiac output was reduced, whether as a result of cardiac disease or of diminution in blood volume. When the second mechanism of oliguria was operating, it dominated the first mechanism, so that the body was no longer normally responsive to changes in plasma-electrolyte concentration. For example, in cardiac or nephrotic œdema, the plasma-salt concentration might be low without stimulating a water diuresis. Conversely, in dehydration salt might be retained although the salt content of the plasma was already high. In such patients, protein breakdown caused an osmotic diuresis, and the high urine volume might be misinterpreted as a sign that adequate water was being given.

For a long time he had thought that the only meaning of the third mechanism (diurnal rhythm) was to make the study of renal function more difficult; but it was in fact useful in avoiding nocturia and also in preventing salt and water retention during the day, which might give us œdema of the legs in the upright posture. In healthy people, diurnal rhythm was the dominant cause of change in salt and water excretion, so that at night salt and water excretion were low, although in terms of the second mechanism one might expect them to be high because of the increased venous return on lying down. Quite moderate circulatory insufficiency ht alter this, with reversal of the urine diurnal thm, and excretion of salt and water mainly through night. In patients treated with adrenocorticotropic mone (A.C.T.H.) or cortisone, the diurnal rhythm of and water excretion was less evident, and they readily eloped nocturia. In Dr. Borst's view, concomitant nges in salt and water excretion could be independent changes in glomerular filtration, and there was no dence that the tubular response to changes in cardiac tput was controlled by the adrenal cortex: in fact, tients with Addison's disease behaved as normals in s respect.

---

RÔLE OF THE ADRENAL CORTEX

Dr. F. T. G. **Prunty** (London) emphasised that nsfers of water and electrolytes from one phase of dy-fluid to another might be as important as changes excretion. Although the relation between water and ctrolyte controlled the "long-term state" of the ganism, it was necessary to study the separate effects the adrenal cortex on water and on salt excretion.

Patients with Addison's disease did not give a normal sponse to water ingestion, even when they were aintained with deoxycortone. Also they tended to crete excess of water during the night. Normal water uresis could be restored by giving 100 mg. of cortisone ily. It had been postulated that cortisone acted by activating posterior pituitary hormone; but the sponse of a patient with Addison's disease to pitressin d been unaffected by cortisone. Patients with hypotuitarism likewise had impaired water diuresis, and them both A.C.T.H. and cortisone corrected this normality.

There was great individual variation in the effect of .T.H. on sodium and chloride excretion. Some patients owed only a transient retention of these ions, with er a negative balance in spite of continued hormone ministration. Others had prolonged retention, with nical œdema requiring the use of mercurial diuretics. a patient with Addison's disease, cortisone was effective by comparison with deoxycortone, and even emed to antagonise the salt-retaining effect of deoxyrtone. It was possible that there was a natural adrenal rmone predominantly concerned with electrolyte metalism, in view of the demonstration by Tait et al.[3] that rtisone could not account for any significant part of e salt-retaining action of adrenal cortical extract. ere was a good deal of detailed evidence that adrenal rtical hormones promoted a shift of fluid from cells extracellular fluid; this expansion of extracellular lume might affect renal excretion of salt and water dependently of any direct hormone action on the bule cells.

RENAL FAILURE

Prof. **Robert Platt** (Manchester) discussed the rious expedients whereby kidneys whose excretory nction had largely been destroyed by disease continued preserve the water and salt content of the body. In st cases of advanced renal disease, until the last few ys of life, there was neither œdema nor dehydration, d the plasma concentration of sodium and potassium s within normal limits. He and his colleagues had alysed the renal function of rats which had had about ree-quarters of their kidney substance excised. The cretion of urea, creatinine, sodium, potassium, and ter in these animals was strikingly similar to that seen human renal failure; and it might be concluded that e essential disability in human renal failure was merical insufficiency of nephrons, and not a distortion the function of those nephrons which remained. In man renal failure, the blood-urea often remained at an evated but constant level for considerable periods, and such circumstances the daily output of urea must be normal. This meant that each of the surviving nephrons must be excreting perhaps five times the amount of urea which a nephron in a normal kidney would be excreting; in other words, there must be a continuous osmotic diuresis. This could account for the polyuria of renal failure, and also for the diminished reabsorption of sodium. There must be diminished reabsorption of sodium, for the filtered load of sodium would be reduced in proportion to the filtration-rate, whereas the excretion of sodium was within normal limits. The excretion of potassium in the urine sometimes exceeded the calculated amount of potassium filtered by the glomeruli, showing secretion of potassium by the tubules; and there was sometimes evidence that the tubules were secreting water, or at least a hypotonic fluid. This was easier to demonstrate in renal failure, because of the low glomerular filtration of water and other substances; but there was no reason to suppose it did not happen in the normal kidney. Study of the performance of the failing kidney suggested that the patient's interests could be best served by allowing him a liberal intake of salt and water, but restricting protein to 30–40 g. daily.

DIABETIC COMA

Dr. **René S. Mach** (Geneva) said that the amount of water and electrolyte lost through the kidney in diabetic coma could be assessed either by stopping insulin in a patient during a balance experiment, or by observing the amounts retained during recovery from natural coma. Large amounts of sodium and chloride were lost; this came mostly from the extracellular fluid, but some might come from the bones. In acidosis intracellular sodium was often decreased, and it was not known whether some of the sodium lost in diabetic coma came from the cells. Potassium was also lost in large amount, mainly from the intracellular compartment; the potassium lost could not be accounted for by protein breakdown. Water was also lost—mainly through the kidneys but to some extent also by hyperventilation and by vomiting. The plasma levels of sodium and chloride might be normal, but were more commonly reduced owing to glucose infusions. Usually the plasma level of potassium was not reduced at first, but fell during treatment. Several factors were concerned in the expansion of extracellular fluid, the increased urinary loss of potassium during saline infusion, and the entry of potassium into the cells during glycogen synthesis. The loss of water and electrolytes in the urine was evident before there was significant acidosis, and was then related to the increasing glycosuria. The onset of acidosis increased the loss of sodium and potassium. Keto-acids were excreted in combination with base; also, acidosis lowered the valency of cellular organic anions, and so made base available for excretion.

Clinically, the loss of extracellular electrolyte and water led to reduced blood volume, with peripheral vascular collapse and renal ischæmia. During recovery, the fall in serum-potassium might cause muscle paralysis, gasping respiration, and myocardial failure. Hypertonic glucose solutions were contra-indicated in treating diabetic coma, for they aggravated the osmotic diuresis and so the loss of water and electrolytes.

DISCUSSION

Dr. G. **Sala** (Italy) described studies he had made on the effect of cortisone on water diuresis in patients with Addison's disease. He had found some increase in the glomerular filtration-rate. Dr. E. **Coelho** (Lisbon) discussed the plasma-potassium in Addison's disease. He had found that the serum-potassium level might bear little relation to the total body content of potassium, and he showed electrocardiograms which illustrated the effect of changes in potassium metabolism on the heart. Dr. E. **Azérad** (France) had shown that in normal

Tait, J. F., Simpson, S. A., Grundy, H. M. *Ibid*, 1952, i, 122.

subjects about 80% of the filtered potassium was reabsorbed.

Dr. L. WISLICKI (Jerusalem) had observed that nicotinamide caused a notable suppression of urine flow even after diuresis had been induced. This antidiuresis still occurred in hypophysectomised animals and so was presumably independent of the antidiuretic hormone mechanism. Although there was some drop in blood-pressure, the antidiuresis lasted for some hours after the blood-pressure had returned to normal. Examination of the kidneys showed hydropic degeneration of the tubule cells, and he concluded that nicotinamide had a direct toxic action on tubular function.

Second Session

Sir HAROLD HIMSWORTH, who took the chair at the second session, cautiously disclaimed any special knowledge of the subject other than by way of intellectual inheritance from his predecessor in the chair of medicine at University College, Sidney Ringer. Ringer's laboratory assistant had used tap water instead of distilled water in preparing perfusion solutions, and the impact of this chance on Ringer's prepared mind had really paved the way for the present expert discussion.

UNDERNUTRITION

Prof. R. A. MCCANCE, F.R.S., and Miss E. M. WIDDOWSON, D.SC. (Cambridge) described some of the ways in which the composition of the body was affected by undernutrition. Some of these had long been familiar, such as the decrease in fat and the small size of the heart, liver, and muscles. Improved methods of analysis, and the breakdown of body composition into fat, water, and "lean body mass" had helped to define the changes. Their own studies had shown that the proportion of the body occupied by extracellular fluid was always increased in undernutrition. None of the explanations for this increase in extracellular fluid was entirely adequate. They believed that replacement of body space previously occupied by fat and cellular tissue was an important cause of the increase in extracellular fluid. A lowered concentration of plasma-proteins and a high-salt intake would aggravate œdema. Although an increase in extracellular fluid was constant, clinical œdema might be absent in undernutrition—a fact appreciated by Dürer, who had drawn "Hunger" as an emaciated horseman without œdema.

Dr. McCance and Dr. Widdowson had analysed more closely the small size of the liver in undernutrition. By estimation of the ribonuclease content of the liver and of the individual liver cell, the number of liver cells could be computed; and it appeared that in undernutrition the liver cells were individually shrunken—a finding which had been anticipated qualitatively by the histologists of the last century.

CELLULAR HYPERHYDRATION

Dr. J. HAMBURGER (Paris) discussed a syndrome of cellular hyperhydration which was becoming recognised as a result of increasing awareness of the distinction between extracellular and cellular fluid. The syndrome could be produced experimentally either by reducing the extracellular osmotic pressure by water infusion, or by exposing the cells to a variety of toxic agents, including cyanide, histamine, carbon dioxide, and acids. A combination of experimental studies with clinical observations had led him to delineate a clinical picture whose chief features were nausea and anorexia, weakness, headache, cramps, and convulsions. There was oliguria and some nitrogen retention. Laboratory investigation showed an increased difference between estimates of total body-water and extracellular fluid. There was an increase in mean corpuscular volume, and a fall in the effective osmotic pressure of plasma. It was important to recognise the syndrome clinically, for the patient might otherwise be treated with water or glucose solution, whereas it responded well to hypertonic saline. Cellular overhydration might sometimes coexist with extracellular overhydration, in which case further salt should not be given; in such cases he had seen good results from hypertonic intestinal perfusion, which removed water from the cells without adding salt to the body.

BASE-BINDING BY SERUM-PROTEIN

Dr. O. J. BROCH (Oslo) discussed hyponatræmia and the base-binding effect of serum-proteins. A low serum-sodium was not uncommon in cachectic states, especially with fever, and giving salt might not raise the serum-sodium level. He had observed patients in whom the total base content of the serum was low but the determined anions (HCO_3 and Cl) were normal, so that there was an "acid surplus" of as much as 21 m.eq. per litre in one patient with hepatic cirrhosis. He attributed this to a diminution in the base-binding capacity of serum-protein. Conversely, it was possible in patients with liver cirrhosis to increase the total base of serum without increasing the anion content; this pointed to an increase in the base-binding by protein. Experimental work in the distribution of electrolytes between serum and extracellular fluid had supported the view that the serum-proteins could bind different amounts of base under different conditions; in this way they could considerably influence osmotic regulation within the body. *When hyponatræmia was due to change in the base-binding power of serum-protein, there was no disturbance of water equilibrium, and no indication therefore for giving salt in treatment.*

RESPONSE TO INJURY

Mr. A. W. WILKINSON (Edinburgh) reviewed the disturbances in body-fluids which were likely to be met with in surgical patients. Any injury, even a surgical operation, was followed by profound metabolic changes, with marked alteration in the urinary output of nitrogen, water, and electrolytes. There was evidence that the adrenal cortex was concerned in these changes, which represented a normal response to injury, and could not readily be modified. In most cases the body could withstand these metabolic distortions without parenteral therapy other than blood-transfusion; but losses of body-fluids might lead to rapid depletion of water and electrolytes, and necessitate parenteral replacement therapy.

Some patients, notably those with œsophageal or pyloric obstruction, were already partly starved and depleted of potassium. Adequate preoperative treatment was needed in some patients to promote wound healing. Although fistulæ only rarely complicated upper abdominal surgery, they were important when they occurred, because large amounts of water and electrolytes were lost but it was not always possible to collect and measure the discharges. In the presence of inflammation, sodium was retained by the kidneys, and might produce distortion in the internal distribution of body-fluid. Alkalosis and acidosis were less important clinically than changes in sodium and potassium distribution. Other surgical conditions which demanded close attention to body-fluid balance were ileostomy, peritonitis, and intestinal obstruction.

DISCUSSION

Dr. D. A. K. BLACK (Manchester) suggested that, since clinical syndromes of electrolyte depletion usually involved several electrolytes, the effects on other electrolytes of induced depletions of one electrolyte required further study. As an example, he showed that induced potassium depletion led to sodium retention if sodium was available in the diet. There was expansion of extracellular fluid, and this might be a small-scale replica of the expansion found in undernutrition. Clinically, there was some evidence that sodium retention and alkalosis might be advantageous in mitigating the effects of potassium loss.

In patients with pyloric stenosis Dr. A. Svanborg (Stockholm) had encountered alkalosis, which was associated with low serum-potassium, and responded to potassium but not to sodium salts.

Dr. M. Soriano-Jiménez (Madrid) had found high titres of antidiuretic substances in the urine of patients with œdema and ascites of hepatic or renal origin. Dr. A. Gajdos (France), using the antipyrin method, had found little difference in the water content of the body of normal subjects and of patients with liver disease. Dr. Ask-Upmark (Norway) had seen osteomalacia follow gastric resection in several patients; he had reported this some years ago, but had not seen other reports of its occurrence.

THE NEUROTROPIC VIRUSES

Sir Russell Brain, who presided at the session on this subject, said that poliomyelitis either had become commoner or was being recognised more often. The study of it had increased in complexity and now attracted attention widely.

POLIOMYELITIS AND COXSACKIE GROUP

Dr. John Paul (Yale), in opening the discussion, said that man himself was the principal source of infection with the poliomyelitis virus. Insects such as flies and cockroaches could harbour virus, but these were not essential agents for spread. The new method of tissue culture devised by J. F. Enders, of Boston, had made some investigations possible in the test-tube, and the era of experimental infection of monkeys, which had held back research because of expense, was perhaps over. The identification of strains had become easier. The Lansing strain, the first to be named, was outnumbered by the much more common Brunhilde strain; the Leon strain was comparatively rare. Immunological tests had shown that myelitis was unusual in systemic infection with the virus. Children withstood this better than adults, in whom the onset was more insidious, two distinct bouts of fever were less common, the illness was longer, pain in the limbs and back was more pronounced, and the prognosis was more serious. At present 25% of those attacked were over 15 years of age. Provoking influences, such as trauma, stress, surgical operations, and immunisations, affected the host; and environmental influences—particularly climate and season—affected the virus. The greatest change in the natural history of the disease was, however, associated with hygiene. In crowded cities, where the standard of living was low, children were born with a high titre of antibodies: this titre rapidly fell but during childhood rose so that by the age of 15 most children had immunity. A high antibody titre was not the same as a high level of immunity, but it did show "footprints of past infections." In these overcrowded communities anterior poliomyelitis remained an endemic disease of young children—i.e., infantile paralysis. The North Alaskan Eskimo showed a completely different picture. In children there was hardly any evidence of immunity; and when the disease occurred it was in epidemic form, attacking adults as well as children. Between these extremes there was every graduation.

Dr. Paul believed that poliomyelitis was not a respiratory infection, but that the usual portal of entry was the mouth. Why warm weather favoured the spread was unknown. Prevention was the hope. To rid the world of the virus was probably impossible; and to be free of endemicity, like Eskimos, carried severe risks. Immunisation was in its infancy; there was no adequate vaccine, and certainly none specific to each of the three strains, though repeated tissue culture might alter the property. Courage would be needed to test on a large scale a vaccine which would ultimately have to be assessed on man. Gamma-globulin given to exposed individuals was another possibility; but results with it were not yet known.

Dr. H. von Magnus (Copenhagen) described the diseases caused by Coxsackie viruses; these viruses were now recognisable by the fact that in suckling mice they gave rise to myositis, pancreatitis, &c. The presence of virus and positive immunological tests had to be interpreted most carefully because double infection was common. Paralysis in a patient with a positive culture of Coxsackie (C) virus who later developed immunological evidence of infection was probably never due to C virus but to a poliomyelitis virus which was a co-traveller. The 16 strains of C virus caused a medley of illnesses, of which herpangina, epidemic myalgia, and short-lived fever were the commonest. Herpangina usually manifested itself with headache, pyrexia, and a sore throat caused by a vesicular enanthem in the tonsillar region. In both herpangina and Bornholm disease infection with Coxsackie virus was constantly present. Possibly some of the "P.U.O.s" now known to be caused by a similar virus would later be recognised as distinct clinical entities. Because of multiplicity of types of C virus, routine laboratory investigation was impossible.

Dr. W. Ritchie Russell (Oxford) said that the acute case of poliomyelitis made exacting demands on doctors and nurses. Continuity of treatment, preferably in a large general hospital or in a special hospital, was desirable provided patients could be nursed so as to prevent spread of infection. The latent period between infection and manifestation of possible paralytic symptoms needed the most careful supervision. Sedation was desirable, although the best sedative was undetermined. The simplest tests, such as asking a child to kiss his knee three times a day, were desirable; and children should be protected against exhaustive muscle testing in the prodromal period. Even transfer to hospital carried a risk. In cases where disturbed respiratory function was suspected, passive breathing in a respirator possibly had advantages. Early diagnosis would be more important if a host-cell interference drug was discovered; and mobile teams might be necessary. Treatment by physiotherapy was important. There was no room for timid gentleness after the acute stage; fatigue of muscle then had no deleterious effect, and movements to prevent spasm were beneficial. Instruments for accurate measurement of muscle recovery were useful. Pharyngeal microphones overcame some of the difficulties of noisy respirators. Bulbar cases were best nursed out of respirators, so that they could have postural drainage.

DISCUSSION

Dr. W. N. Pickles (Aysgarth) showed an interesting chart of five cases of Bell's palsy occurring at the same times as herpes zoster and chickenpox. These were the only cases of Bell's palsy in his practice in 20 years.

Prof. C. H. Stuart-Harris (Sheffield) described an epidemic of herpangina in four children aged 3 to 13. Fæces in dilution of 1 in 10 million yielded C virus.

Dr. O. Thordarsen said that Bornholm disease had been present in Iceland since 1847. It had caused outbreaks each year since 1928. In 1947, out of 57,000 people in Reykjavik 225 were attacked; and C virus was present in a high percentage of random samples.

Dr. L. Condorelli said that in Italy infection with Coxsackie virus caused few signs of fever but principally neurological symptoms—sometimes encephalitic and sometimes, apoplectic—and at other times lumbar tenderness. Despite very high counts in the cerebrospinal fluid recovery was usually complete in 14 days.

Dr. R. E. SMITH (Rugby) said that just as anterior poliomyelitis was more severe in the adult, so also was posterior poliomyelitis or herpes zoster. Reports on treatment with vitamin B suggested that the ageing posterior-born cells could be supported in their combat with the virus. Two clinical types were recognisable, one of which was associated with chickenpox.

Prof. E. OLIVER (Madrid) described cases of Coxsackie-like infections associated with disease of the central nervous system and hepatic and pancreatic lesions.

No-one answered categorically the only question asked: Does lumbar puncture aggravate in poliomyelitis?

ANTIBIOTICS IN MAN

At the concluding session, with Sir LIONEL WHITBY in the chair, Sir ALEXANDER FLEMING, F.R.S., discussed antibiotics in general terms, with more special reference to the factors to be taken into account in selecting the right drug or combination of drugs in the treatment of any infection. All the antibiotics, he said, were to some extent selective in their action: though some might be effective against a wider range of micro-organisms than others, yet none were inhibitory to all bacteria. Consequently in antibiotic therapy there were two main problems. First it was necessary to use an antibiotic effective against the infecting microbe. This necessitated a considerable amount of laboratory control, not only for identification of the organism but also for determination of its sensitivity in vitro to the various antibiotics. Secondly, the physician must ensure that the antibiotic reached the organisms in the body in a concentration high enough to destroy them. This problem, Sir Alexander said, was often neglected. It was necessary to think further than the mere introduction of an antibiotic into the blood-stream, for this was often insufficient to allow penetration into an abscess cavity or across the blood-brain and other barriers.

He then turned to the question of combinations of antibiotics in therapy. Such combinations might be considerably more effective than the simple summation of the individual actions of the drugs alone, though it appeared from the work of Jawetz and his colleagues that in many cases the addition of one antibiotic to another might cause a diminution of the activity of both. To illustrate the complexities of the subject, the example was quoted of an organism which was sensitive to penicillin in vitro. The addition of aureomycin caused a lessened response to penicillin, the two drugs being antagonistic to each other. When, however, the same organism was made artificially resistant to penicillin, the addition of aureomycin caused an increased response, the two drugs now acting synergistically.

Finally, Sir Alexander mentioned the subject of nomenclature. By definition, one of the fundamental features of an antibiotic, he said, was its production by a living organism. But 'Chloromycetin' was now produced solely by synthetic means. Should this substance, therefore, be cast out of the antibiotic fold and listed merely as a chemotherapeutic agent, like arsphenamine, the sulphonamides, or isonicotinic acid hydrazide? One might drop the term antibiotic and call all these substances chemotherapeutic agents, but on the whole he felt it would be better to continue the present practice of calling a substance an antiobiotic if it was originally produced by a living organism.

DOSES AND COMPLICATIONS

Dr. F. MAGRASSI (Naples) devoted his talk to various aspects of the posology of penicillin, streptomycin, aureomycin, and chloramphenicol, and to the complications which can arise from the use of these substances. In the earliest days of penicillin therapy, he said, there was thought to be an exact correspondence between the antibacterial power of the antibiotic in vitro and its activity in vivo, and participation by the defensive mechanisms of the body was held to be insignificant. Today this conception had lost most of its value, not only for penicillin but also for streptomycin, aureomycin, and chloramphenicol. Though in many cases one found a correspondence between the sensitivity of an infecting organism in vitro and its response to an antibiotic in vivo, there were cases in which antibiotics were clinically effective even though the organism appeared resistant in vitro. Similarly, in some instances the organism might be highly sensitive in vitro to an antibiotic which had negligible value clinically. Many of these latter results could be explained by the failure of the antibiotic to reach the organism in sufficient concentration by the route employed.

The complications sometimes associated with antibiotic therapy might arise through various mechanisms. Direct toxicity varied considerably with different antibiotics. The toxicity of penicillin was so low that it could be regarded as practically non-existent, whereas that of streptomycin was considerable. Complications arising from hypersensitivity to antibiotics were numerous: they were similar to allergic reactions to other drugs and affected commonly the nervous, cutaneous, and digestive systems. In this category of complications Dr. Magrassi discussed the blood dyscrasias following chloramphenicol. There was, he said, no evidence of direct toxicity of the drug on the bone-marrow, and it seemed likely that the disorders were allergic manifestations in patients hypersensitive to the antibiotic.

Another important group of complications of antibiotic therapy were those resulting from the action of the drugs on the bacterial flora of the body. The organisms causing the infection for which an antibiotic was being administered might become resistant to the drug and necessitate a revision of treatment. Alternatively, elimination of the infecting organisms might be followed by overgrowth of other bacteria or fungi resistant to the antibiotic. These might cause extension of the disease if their pathogenic propensities were sufficient. Finally, the possibility of disturbances in the synthesis or utilisation of vitamins and other substances by interference with the normal intestinal bacterial ecology must be taken into account in the management of antibiotic therapy.

EFFECTIVE CONCENTRATIONS

Prof. ALAN KEKWICK (London) said that the standard doses of the drugs were, in the main, designed to produce bacteriostatic or bactericidal concentrations in the blood, but such levels did not necessarily reflect an equivalent therapeutic effectiveness in other tissues. Knowledge of the distribution of antibiotics throughout many of the tissues in man was still largely incomplete, though a good deal of information was available regarding the concentrations attainable in many body-fluids and cavities. Penetration through the blood-brain barrier—notoriously poor for penicillin, even after large doses—continued to give cause for concern. Hardly any terramycin reached the cerebrospinal fluid from the blood, while the level of streptomycin was only a fifth to a tenth of that in the plasma. Aureomycin concentrations of about half that in the plasma might be attained only after a delay of several days. Chloramphenicol, however, penetrated with the greatest facility, giving levels up to three-quarters the plasma level in a very short time. Ease of penetration of these five antibiotics into body cavities followed a similar pattern to that of the cerebrospinal fluid. In the pleura the concentrations of penicillin, streptomycin, and terramycin that might be attained were about half to a quarter of the plasma levels. Aureomycin penetrated better, but only after considerable delay, while chloramphenicol rapidly gave high concentrations. Similar penetrative powers were observed for the pericardial sac and the peritoneal cavity, concentrations in the latter being somewhat higher than those in the pleural cavities. In the nasal sinuses and the aqueous and vitreous of the eye the levels of each antibiotic attainable were considerably lower than those elsewhere.

All five substances were excreted by the kidney. About 75% of the penicillin or terramycin administered might be recovered in biologically active form from the urine, while about 50% of streptomycin was recoverable. Both aureomycin and chloramphenicol were largely destroyed in the body, and only 15% of the former and 10% of the latter were excreted in the urine in a form active against bacteria.

Penicillin and streptomycin had the advantage over the other three antibiotics that they were largely nonirritant and could be introduced in quite large doses into the subarachnoid space, from which some absorption into the blood-stream occurred, giving levels about 10% of those in the cerebrospinal fluid. There was very little absorption from the pleural and peritoneal cavities, especially when these were inflamed.

The amount of each antibiotic absorbed after oral administration varied considerably. About 20% of penicillin was absorbed by this route, the remainder being destroyed by bacteria in the large intestine. Streptomycin was even more poorly absorbed (about 5%), but since the remainder was not destroyed it was available in active form for use in purely intestinal infections. Aureomycin was absorbed fairly well from the intestine and was unique amongst the antibiotics in current use in that it was taken up by the reticuloendothelial system, from which it was then slowly released into the blood-stream. Chloramphenicol was the most rapidly and efficiently absorbed antibiotic, while terramycin, though fairly readily absorbed, seemed to show a threshold of maximum absorption for a dose of about 1 g. every eight hours. No additional uptake occurred when this dose was increased.

IMPACT OF ANTIBIOTICS

Prof. C. JIMÉNEZ-DIAZ (Madrid) spoke of the various harmful effects of the antibiotics and also of certain of their beneficial actions other than the eradication of infections. Among the harmful effects, he discussed in some detail the toxicity of antibiotics, especially in relation to allergic phenomena. Though these were manifested frequently by simple cutaneous responses, sometimes there were more serious reactions such as the polyarteritis occasionally seen after penicillin administration. Direct toxic effects of antibiotics were uncommon. Lesions of the 8th cranial nerve might follow the use of streptomycin, and occasionally this drug was responsible for thrombocytopenic purpura, leucopenia, and aplastic anæmia. Of considerable importance among the harmful effects was the development of resistance of bacteria to antibiotics. The frequency of occurrence of penicillin-resistant staphylococci had risen markedly in recent years, and resistance had been observed in various bacteria after treatment with terramycin, aureomycin, and chloramphenicol. Sometimes an organism developed resistance simultaneously to two antibiotics during treatment with one of them. This phenomenon of "crossed resistance" was seen most frequently between aureomycin and terramycin or chloramphenicol.

Dr. Jiménez-Diaz laid great stress on the importance of normal bacterial symbiotic relationships in the body and on the disorders that may result from their disturbance. By interference with the intestinal bacteria which normally assisted digestion, antibiotics might give rise to malnutrition. This had been seen both in experimental animals and in clinical practice. Digestive disturbances, varying from mild dyspepsia to severe diarrhœa and vomiting, might result from the disturbance of bacterial symbiosis, which opened the way to secondary invasion by organisms resistant to the antibiotic in use. In the intestinal tract these organisms were usually yeasts, while in the respiratory system coliform bacilli or resistant staphylococci might assume predominance.

From harmful effects Dr. Jiménez-Diaz then turned to some aspects of antibiotic usage very different from those which are generally familiar. These reactions, whose character is still little known, concern the metabolism and respiration of tissues and organs, general nutrition and growth, and the repair of tissue injuries. As an example of such activities he cited the beneficial effect of aureomycin in infective hepatitis. It seems that the antibiotic has no direct action on the virus, but acts by improving the nutrition of the hepatic cells. Some cases of hepatic cirrhosis had, he said, shown surprisingly good response to aureomycin. Terramycin, too, seemed to be of considerable value in the treatment of experimental cirrhosis in animals. He predicted, in conclusion, that the future would bring to light many useful actions of the antibiotics apart from their purely antibacterial rôles.

DISCUSSION

The discussion which followed the opening papers covered a wide variety of aspects of antibiotic action, ranging from electron micrographs illustrating the effect of penicillin on *Salmonella typhi* to the treatment of peptic ulcers with terramycin (Dr. NAJIB-FARAH, Alexandria). In the latter instance it seemed that many factors other than the terramycin must have played their part in the beneficial responses of the patients described, and it would be premature to conclude that terramycin is now the remedy of choice for these conditions.

Commenting on the so-called barriers to the passage of antibiotics into certain tissues, Prof. C. D. DE LANGEN (Utrecht) spoke of the importance of adequate capillary pressure and described the case of a severely shocked patient with pneumonia. Initially this patient showed no response to penicillin, but after a blood-transfusion the infection rapidly subsided under the influence of the same antibiotic. Professor de Langen interpreted this response as indicating that the penicillin could not reach the infected tissues unless there was enough pressure to drive it out of the capillaries.

Among the speakers who discussed the harmful effects of antibiotics was Dr. K. G. BENGTSSON (Stockholm), who reported a case in which typical pernicious anæmia developed in a patient who had received about 100 grammes of chloramphenicol in about six weeks. The anæmia responded satisfactorily to liver therapy.

A new note of caution was struck by Dr. B. OLHAGEN (Stockholm), who described several cases in which acid-fast bacilli had appeared in the sputum of patients receiving antibiotics. Guineapig inoculation showed that these organisms were not tubercle bacilli, and it was thought that they were a species of acid-fast fungus. Dr. Olhagen thought it advisable to carry out animal inoculation tests whenever acid-fast bacilli are found in a specimen of sputum; but such a procedure, however desirable, would certainly present difficulties in laboratories handling large numbers of tuberculous specimens.

☞ Members of the congress paid visits, in small parties, to many of the principal London hospitals, and also travelled more widely. Those attending numbered more than 500, from over 30 countries.

sometimes apoplectic—and at other times lumbar tenderness. Despite very high counts in the cerebrospinal fluid recovery was usually complete in 14 days.

There was, he said, no evidence of direct toxicity of the drug on the bone-marrow, and it seemed likely that the disorders were allergic manifestations in patients hypersensitive to the antibiotic.

Another important group of complications of antibiotic therapy were those resulting from the action of the drugs on the bacterial flora of the body. The organisms causing the infection for which an antibiotic was being administered might become resistant to the drug and necessitate a revision of treatment. Alternatively, elimination of the infecting organisms might be followed by overgrowth of other bacteria or fungi resistant to the antibiotic. These might cause extension of the disease if their pathogenic propensities were sufficient. Finally, the possibility of disturbances in the synthesis or utilisation of vitamins and other substances by interference with the normal intestinal bacterial ecology must be taken into account in the management of antibiotic therapy.

EFFECTIVE CONCENTRATIONS

Prof. ALAN KEKWICK (London) said that the standard doses of the drugs were, in the main, designed to produce bacteriostatic or bactericidal concentrations in the blood, but such levels did not necessarily reflect an equivalent therapeutic effectiveness in other tissues. Knowledge of the distribution of antibiotics throughout many of the tissues in man was still largely incomplete, though a good deal of information was available regarding the concentrations attainable in many body-fluids and cavities. Penetration through the blood-brain barrier—notoriously poor for penicillin, even after large doses—continued to give cause for concern. Hardly any terramycin reached the cerebrospinal fluid from the blood, while the level of streptomycin was only a fifth to a tenth of that in the plasma. Aureomycin concentrations of about half that in the plasma might be attained only after a delay of several days. Chloramphenicol, however, penetrated with the greatest facility, giving levels up to three-quarters the plasma level in a very short time. Ease of penetration of these five antibiotics into body cavities followed a similar pattern to that of the cerebrospinal fluid. In the pleura the concentrations of penicillin, streptomycin, and erramycin that might be attained were about half to quarter of the plasma levels. Aureomycin penetrated etter, but only after considerable delay, while chloramhenicol rapidly gave high concentrations. Similar enetrative powers were observed for the pericardial ac and the peritoneal cavity, concentrations in the atter being somewhat higher than those in the pleural cavities. In the nasal sinuses and the aqueous and vitreous of the eye the levels of each antibiotic attainable were considerably lower than those elsewhere.

All five substances were excreted by the kidney. About 75% of the penicillin or terramycin administered might be recovered in biologically active form from the urine, while about 50% of streptomycin was recoverable. Both aureomycin and chloramphenicol were largely destroyed in the body, and only 15% of the former and 10% of the latter were excreted in the urine in a form active against bacteria.

Penicillin and streptomycin had the advantage over the other three antibiotics that they were largely nonirritant and could be introduced in quite large doses into the subarachnoid space, from which some absorption into the blood-stream occurred, giving levels about 10% of those in the cerebrospinal fluid. There was very little absorption from the pleural and peritoneal cavities, especially when these were inflamed.

The amount of each antibiotic absorbed after oral administration varied considerably. About 20% of penicillin was absorbed by this route, the remainder being destroyed by bacteria in the large intestine. Streptomycin was even more poorly absorbed (about 5%), but since the remainder was not destroyed it was available in active form for use in purely intestinal infections. Aureomycin was absorbed fairly well from the intestine and was unique amongst the antibiotics in current use in that it was taken up by the reticulo-endothelial system, from which it was then slowly released into the blood-stream. Chloramphenicol was the most rapidly and efficiently absorbed antibiotic, while terramycin, though fairly readily absorbed, seemed to show a threshold of maximum absorption for a dose of about 1 g. every eight hours. No additional uptake occurred when this dose was increased.

IMPACT OF ANTIBIOTICS

Prof. C. JIMÉNEZ-DIAZ (Madrid) spoke of the various harmful effects of the antibiotics and also of certain of their beneficial actions other than the eradication of infections. Among the harmful effects, he discussed in some detail the toxicity of antibiotics, especially in relation to allergic phenomena. Though these were manifested frequently by simple cutaneous responses, sometimes there were more serious reactions such as the polyarteritis occasionally seen after penicillin administration. Direct toxic effects of antibiotics were uncommon. Lesions of the 8th cranial nerve might follow the use of streptomycin, and occasionally this drug was responsible for thrombocytopenic purpura, leucopenia, and aplastic anæmia. Of considerable importance among the harmful effects was the development of resistance of bacteria to antibiotics. The frequency of occurrence of penicillin-resistant staphylococci had risen markedly in recent years, and resistance had been observed in various bacteria after treatment with terramycin, aureomycin, and chloramphenicol. Sometimes an organism developed resistance simultaneously to two antibiotics during treatment with one of them. This phenomenon of "crossed resistance" was seen most frequently between aureomycin and terramycin or chloramphenicol.

Dr. Jiménez-Diaz laid great stress on the importance of normal bacterial symbiotic relationships in the body and on the disorders that may result from their disturbance. By interference with the intestinal bacteria which normally assisted digestion, antibiotics might give rise to malnutrition. This had been seen both in experimental animals and in clinical practice. Digestive disturbances, varying from mild dyspepsia to severe diarrhœa and vomiting, might result from the disturbance of bacterial symbiosis, which opened the way to secondary invasion by organisms resistant to the antibiotic in use. In the intestinal tract these organisms were usually yeasts, while in the respiratory system coliform bacilli or resistant staphylococci might assume predominance.

From harmful effects Dr. Jiménez-Diaz then turned to some aspects of antibiotic usage very different from those which are generally familiar. These reactions, whose character is still little known, concern the metabolism and respiration of tissues and organs, general nutrition and growth, and the repair of tissue injuries. As an example of such activities he cited the beneficial effect of aureomycin in infective hepatitis. It seems that the antibiotic has no direct action on the virus, but acts by improving the nutrition of the hepatic cells. Some cases of hepatic cirrhosis had, he said, shown surprisingly good response to aureomycin. Terramycin, too, seemed to be of considerable value in the treatment of experimental cirrhosis in animals. He predicted, in conclusion, that the future would bring to light many useful actions of the antibiotics apart from their purely antibacterial rôles.

DISCUSSION

The discussion which followed the opening papers covered a wide variety of aspects of antibiotic action, ranging from electron micrographs illustrating the effect of penicillin on *Salmonella typhi* to the treatment of peptic ulcers with terramycin (Dr. NAJIB-FARAH, Alexandria). In the latter instance it seemed that many factors other than the terramycin must have played their part in the beneficial responses of the patients described, and it would be premature to conclude that terramycin is now the remedy of choice for these conditions.

Commenting on the so-called barriers to the passage of antibiotics into certain tissues, Prof. C. D. DE LANGEN (Utrecht) spoke of the importance of adequate capillary pressure and described the case of a severely shocked patient with pneumonia. Initially this patient showed no response to penicillin, but after a blood-transfusion the infection rapidly subsided under the influence of the same antibiotic. Professor de Langen interpreted this response as indicating that the penicillin could not reach the infected tissues unless there was enough pressure to drive it out of the capillaries.

Among the speakers who discussed the harmful effects of antibiotics was Dr. K. G. BENGTSSON (Stockholm), who reported a case in which typical pernicious anæmia developed in a patient who had received about 100 grammes of chloramphenicol in about six weeks. The anæmia responded satisfactorily to liver therapy.

A new note of caution was struck by Dr. B. OLHAGEN (Stockholm), who described several cases in which acid-fast bacilli had appeared in the sputum of patients receiving antibiotics. Guineapig inoculation showed that these organisms were not tubercle bacilli, and it was thought that they were a species of acid-fast fungus. Dr. Olhagen thought it advisable to carry out animal inoculation tests whenever acid-fast bacilli are found in a specimen of sputum; but such a procedure, however desirable, would certainly present difficulties in laboratories handling large numbers of tuberculous specimens.

☞ Members of the congress paid visits, in small parties, to many of the principal London hospitals, and also travelled more widely. Those attending numbered more than 500, from over 30 countries.

sometimes, apoplectic—and at other times lumbar tenderness. Despite very high counts in the cerebrospinal fluid recovery was usually complete in 14 days.

Dr. R. E. SMITH (Rugby) said that just as anterior poliomyelitis was more severe in the adult, so also was posterior poliomyelitis or herpes zoster. Reports on treatment with vitamin B suggested that the ageing posterior-horn cells could be supported in their combat with the virus. Two clinical types were recognisable, one of which was associated with chickenpox.

Prof. E. OLIVER (Madrid) described cases of Coxsackie-like infections associated with disease of the central nervous system and hepatic and pancreatic lesions.

No-one answered categorically the only question asked: Does lumbar puncture aggravate in poliomyelitis?

ANTIBIOTICS IN MAN

AT the concluding session, with Sir LIONEL WHITBY in the chair, Sir ALEXANDER FLEMING, F.R.S., discussed antibiotics in general terms, with more special reference to the factors to be taken into account in selecting the right drug or combination of drugs in the treatment of any infection. All the antibiotics, he said, were to some extent selective in their action: though some might be effective against a wider range of micro-organisms than others, yet none were inhibitory to all bacteria. Consequently in antibiotic therapy there were two main problems. First it was necessary to use an antibiotic effective against the infecting microbe. This necessitated a considerable amount of laboratory control, not only for identification of the organism but also for determination of its sensitivity in vitro to the various antibiotics. Secondly, the physician must ensure that the antibiotic reached the organisms in the body in a concentration high enough to destroy them. This problem, Sir Alexander said, was often neglected. It was necessary to think further than the mere introduction of an antibiotic into the blood-stream, for this was often insufficient to allow penetration into an abscess cavity or across the blood-brain and other barriers.

He then turned to the question of combinations of antibiotics in therapy. Such combinations might be considerably more effective than the simple summation of the individual actions of the drugs alone, though it appeared from the work of Jawetz and his colleagues that in many cases the addition of one antibiotic to another might cause a diminution of the activity of both. To illustrate the complexities of the subject, the example was quoted of an organism which was sensitive to penicillin in vitro. The addition of aureomycin caused a lessened response to penicillin, the two drugs being antagonistic to each other. When, however, the same organism was made artificially resistant to penicillin, the addition of aureomycin caused an increased response, the two drugs now acting synergistically.

Finally, Sir Alexander mentioned the subject of nomenclature. By definition, one of the fundamental features of an antibiotic, he said, was its production by a living organism. But 'Chloromycetin' was now produced solely by synthetic means. Should this substance, therefore, be cast out of the antibiotic fold and listed merely as a chemotherapeutic agent, like arsphenamine, the sulphonamides, or isonicotinic acid hydrazide? One might drop the term antibiotic and call all these substances chemotherapeutic agents, but on the whole he felt it would be better to continue the present practice of calling a substance an antiobiotic if it was originally produced by a living organism.

DOSES AND COMPLICATIONS

Dr. F. MAGRASSI (Naples) devoted his talk to various aspects of the posology of penicillin, streptomycin, aureomycin, and chloramphenicol, and to the complications which can arise from the use of these substances. In the earliest days of penicillin therapy, he said, there was thought to be an exact correspondence between the antibacterial power of the antibiotic in vitro and its activity in vivo, and participation by the defensive mechanisms of the body was held to be insignificant. Today this conception had lost most of its value, not only for penicillin but also for streptomycin, aureomycin, and chloramphenicol. Though in many cases one found a correspondence between the sensitivity of an infecting organism in vitro and its response to an antibiotic in vivo, there were cases in which antibiotics were clinically effective even though the organism appeared resistant in vitro. Similarly, in some instances the organism might be highly sensitive in vitro to an antibiotic which had negligible value clinically. Many of these latter results could be explained by the failure of the antibiotic to reach the organism in sufficient concentration by the route employed.

The complications sometimes associated with antibiotic therapy might arise through various mechanisms. Direct toxicity varied considerably with different antibiotics. The toxicity of penicillin was so low that it could be regarded as practically non-existent, whereas that of streptomycin was considerable. Complications arising from hypersensitivity to antibiotics were numerous: they were similar to allergic reactions to other drugs and affected commonly the nervous, cutaneous, and digestive systems. In this category of complications Dr. Magrassi discussed the blood dyscrasias following chloramphenicol. There was, he said, no evidence of direct toxicity of the drug on the bone-marrow, and it seemed likely that the disorders were allergic manifestations in patients hypersensitive to the antibiotic.

Another important group of complications of antibiotic therapy were those resulting from the action of the drugs on the bacterial flora of the body. The organisms causing the infection for which an antibiotic was being administered might become resistant to the drug and necessitate a revision of treatment. Alternatively, elimination of the infecting organisms might be followed by overgrowth of other bacteria or fungi resistant to the antibiotic. These might cause extension of the disease if their pathogenic propensities were sufficient. Finally, the possibility of disturbances in the synthesis or utilisation of vitamins and other substances by interference with the normal intestinal bacterial ecology must be taken into account in the management of antibiotic therapy.

EFFECTIVE CONCENTRATIONS

Prof. ALAN KEKWICK (London) said that the standard doses of the drugs were, in the main, designed to produce bacteriostatic or bactericidal concentrations in the blood, but such levels did not necessarily reflect an equivalent therapeutic effectiveness in other tissues. Knowledge of the distribution of antibiotics throughout many of the tissues in man was still largely incomplete, though *a good deal of information was available regarding the concentrations attainable in many body-fluids and cavities. Penetration through the blood-brain barrier*—notoriously poor for penicillin, even after large doses—continued to give cause for concern. *Hardly any* terramycin reached the cerebrospinal fluid *from the* blood, while the level of streptomycin was *only* a fifth to a tenth of that in the plasma. Aureomycin concentrations of about half that in the plasma might be attained only after a delay of several days. Chloramphenicol, however, penetrated with the greatest facility, giving levels up to three-quarters the plasma level in a very short time. Ease of penetration of these five antibiotics into body cavities followed a similar *pattern to that of the cerebrospinal fluid.* In the pleura *the concentrations of penicillin,* streptomycin, and terramycin that might be attained were about half to a quarter of the plasma levels. Aureomycin penetrated better, but only after considerable delay, while chloramphenicol rapidly gave high concentrations. Similar penetrative powers were observed for the pericardial sac and the peritoneal cavity, concentrations in the latter being somewhat higher than those in the pleural cavities. In the nasal sinuses and the aqueous and vitreous of the eye the levels of each antibiotic attainable were considerably lower than those elsewhere.

All five substances were excreted by the kidney. About 75% of the penicillin or terramycin administered might be recovered in biologically active form from the urine, while about 50% of streptomycin was recoverable. Both aureomycin and chloramphenicol were largely destroyed in the body, and only 15% of the former and 10% of the latter were excreted in the urine in a form active against bacteria.

Penicillin and streptomycin had the advantage over the other three antibiotics that they were largely non-irritant and could be introduced in quite large doses into the subarachnoid space, from which some absorption into the blood-stream occurred, giving levels about 10% of those in the cerebrospinal fluid. There was very little absorption from the pleural and peritoneal cavities, especially when these were inflamed.

The amount of each antibiotic absorbed after oral administration varied considerably. About 20% of penicillin was absorbed by this route, the remainder being destroyed by bacteria in the large intestine. Streptomycin was even more poorly absorbed (about 5%), but since the remainder was not destroyed it was available in active form for use in purely intestinal infections. Aureomycin was absorbed fairly well from the intestine and was unique amongst the antibiotics in current use in that it was taken up by the réticulo-endothelial system, from which it was then slowly released into the blood-stream. Chloramphenicol was the most rapidly and efficiently absorbed antibiotic, while terramycin, though fairly readily absorbed, seemed to show a threshold of maximum absorption for a dose of about 1 g. every eight hours. No additional uptake occurred when this dose was increased.

INTERNATIONAL CONGRESS OF NEUROPATHOLOGY

The first International Congress of Neuropathology, held in the Palazzo Barberini, Rome, between Sept. 8 and 13, was attended by 414 people from 37 countries. Dr. Mario Gozzano (Rome) was the president, Dr. Lucio Bini (Rome) the secretary-treasurer, and Dr. Armando Ferraro (New York) the secretary-general.

If, said the President in his opening remarks, there was an inherent danger in excessive specialisation, then the remedy lay in collaboration. This was the reason for this first international meeting of neuropathologists; and he was firmly of the opinion that neurology, far from being the loser, would be gaining. The specialty called for new techniques—techniques of thought as well as new methods of investigation—and this was the occasion to pool knowledge so far as the tyranny of time permitted.

DEMYELINATING DISEASES

I. **Hallevorden** (Giessen) rejected outright the hypothesis that multiple sclerosis had its origin in vascular thrombosis: such vascular changes as occurred were to be expected in any inflammatory process. In multiple sclerosis inflammation preceded sclerosis, while demyelination preceded inflammation. The disease was essentially one of myelin dissolution, the ganglion cells and axis-cylinders being relatively spared. The location of the foci suggested that the specific demyelinating substance diffused through the capillary vascular bed and was perhaps also conveyed by the cerebrospinal fluid.

Professor Hallevorden drew an analogy between von Balo's concentric sclerosis and the "ringspot disease" of plants which was known to be viral in origin. The Liesegang phenomenon so clearly represented in the former disease had been accurately mimicked by means of silver-chromate precipitation in a gelatin medium. In von Balo's disease the stratification of the concentric rings was probably the result of the repeated production of antibodies: in the plant disease such antibodies had already been isolated. In his opinion multiple sclerosis was a specific disease and there were no intermediate forms, as had sometimes been postulated, between it and the various varieties of encephalomyelitis; certainly it had no resemblance to the experimental forms of allergic encephalitis. He believed that multiple sclerosis was viral in origin.

J. G. **Greenfield** (London) agreed with the views expressed by King and Meehan (1950): the demyelinating diseases of animals had no similarity to those of man. One could learn much of the process of demyelination by a study of the œdema to be found around tumours, abscesses, and contusion; this was rarely complete and the main commissural tracts, such as the optic radiations and corpus callosum, as well as the subcortical U fibres, tended to be spared. In the affected areas there was comparatively little katabolism of the myelin into neutral fat, the axons showed only a minimal disturbance, and the capillaries remained healthy. The microglial cells were mobilised early and the astrocytes soon began to swell: the oligodendroglia, on the other hand, showed little change. Myeloclasts of either microglial or oligodendroglial origin were to be found in many of the distended myelin-sheaths. Doubtless it was all due to stasis of the tissue fluids and interference with the process of metabolic exchange, but this form of demyelination secondary to œdema might at times be so severe and widespread as to mimic diffuse sclerosis.

Dr. Greenfield said that it was becoming increasingly evident that the subacute form of encephalitis of Dawson (1933) and that described by van Bogaert (1945) were one and the same. Demyelination and sclerosis of the white matter were to be found in both, whether or not inclusion bodies could be found in the nerve-cells. In some instances alteration of the white matter was widespread and severe, but in others slight. The changes in fact might simulate those of diffuse sclerosis except that the U fibres were not spared as in the latter disease and the inflammatory process involved the cortex. He now agreed with van Bogaert that this disease was primarily one of the white matter. The presence of intranuclear inclusion bodies in the oligodendroglia suggested that the demyelination might be secondary to damage to these cells.

Researches on allergic encephalitis led now to the view, long held by Glanzmann and van Bogaert, that acute postexanthematous disseminated encephalomyelitis (characterised by perivenous demyelination), and to an even greater extent the acute hæmorrhagic leucoencephalitis described by Weston Hurst (1941), were essentially allergic in character. In the latter, which differed from the former only in the prominence of the leucocytic exudate and in its tendency to be confined to the central grey matter, acute necrosis of the vessel walls was clearly evident and accounted for the exudation of œdema fluid and fibrin.

He agreed that there was no evidence that demyelination was preceded by inflammation in multiple sclerosis: rather was the reverse the truth. In a recent case where a plaque gave rise to clinical evidence of its appearance eight days before death there was already almost complete loss of myelin, and the only evidence of reaction was to be seen in the earliest phase of microglial activity.

Dr. Greenfield held that our imperfect knowledge of the various forms of diffuse sclerosis justified further analysis. It was in fact customary in pathology to separate our diseases on the basis of a particular cell reaction. He proposed therefore to subdivide these diseases on a basis of myelin metabolism. The first group consisted of those cases in which sudanophilic lipid, some of it anisotropic, was plentiful, suggesting a breakdown of the myelin on classical lines as was to be found in multiple sclerosis, encephalomalacia, and wallerian degeneration. The bulk of the spontaneous cases came into this group. The second group comprised the metachromatic leucodystrophies: in them sudanophilic lipid was either absent or present only in the walls of vessels, its place being taken by material which appeared to be a galactolipid. He believed that in this variety of the disease, which was often familial, there was a constitutional fault in the myelin. In a special late form of it there was evidence of a primary degeneration of the oligodendroglia. The third group comprised those rare instances in which one found clusters of globoid cells containing some relatively immovable substance which was not sudanophilic.

A. **Wolf** (New York) reviewed the various forms of demyelination which had been produced experimentally, and also the spontaneous and allergic diseases of man and animals in which demyelination was apparently the primary process. There were basic similarities between them in that the myelin appeared to be the vulnerable element, but one could not pursue the analogy too far. A disease of known ætiology might show in many forms, whilst a histological picture might be common to more than one ætiological factor. Those diseases of the white matter in man which were thought to be due to an endogenous myelinotoxic agent (eclampsia, porphyria, subacute combined degeneration of the cord, and dysentery) yielded valuable information on the pathology of myelin, but proof was lacking that there was any such toxin in multiple sclerosis. He knew of no evidence to suggest that in multiple sclerosis there was a disorder of lipid metabolism; nor was there evidence of a nutritional factor. Vascular occlusion, when it occurred, surely played only a secondary part. He concluded from a study of the experimental disease, which could now be produced readily not only in the monkey but in the guineapig, the dog, and the mouse, that there was no pathological picture which could be regarded as specific of an allergic reaction. Because of the enhancing effect of the adjuvants of Freund and the preventive action of cortisone, one would have supposed that the experimental allergic encephalomyelitis had for its basis an immunological mechanism, but the value of this hypothesis was lessened by the facts that this disease could not be transmitted passively and that no parallelism had been observed between the production of antibody-fixing complement and the development of the pathological process. Efforts to isolate an active antigen had produced contradictory results.

In the discussion G. **Steiner** (Detroit) produced photomicrographs showing convincingly the presence of leptospira in the lesions of multiple sclerosis. There were three diseases at first thought to be viral in origin which were now known to be due to leptospiræ; multiple sclerosis might turn out to be a fourth. He could not agree that the inflammation was secondary to tissue damage; he regarded it as primary because he had found inflammation in the leptomeninges at some distance from the plaques and even down in the cauda equina.

H. **Pette** (Hamburg) maintained that the pathogenesis of multiple sclerosis must be assessed from clinical studies as well as in the laboratory. He could not accept any evidence so far adduced as being in favour of a viral origin. Virus diseases were expected to show periodic outbreaks. Moreover we had no knowledge of a virus causing demyelination and would not expect that a virus could; a virus by its very nature was parasitic in the cells of the host, but in the disease we were dealing not with cells but with a labile lipid membrane. He knew of no virus which could thrive in a lipid medium. Multiple sclerosis was a specific reaction on the part of the nervous system; but it might, as was believed now to be the case in Boeck's sarcoidosis, be due to one of many ætiological factors. He thought that the disease often depended upon allergy for its manifestations, but he knew of no instance of perivenous encephalomyelitis that had developed into multiple sclerosis. The theory of neuroallergy, which he had advanced in 1931, was now on a firm basis.

D. J. **Trevan** (Beckenham) produced important evidence in the field of comparative pathology. He reported that myelin destruction could occur in dogs infected with a distemper-like virus. The damaged myelin, he argued, might act as an antigen to a reaction of antibody-producing type set up by the myelin, by the virus, or even by both. The antibody produced could react with, and damage, more myelin, which in turn would be released to act as a further antigen. In this way the antibody-producing changes might be prolonged indefinitely after the virus had died out.

C. L. **Cazzullo** (Milan) and G. **Gomirato** (Turin) believed that histobiochemical analysis had been neglected in the study of multiple sclerosis; the rôle of enzymes in this disease might turn out to be important.

G. **Schaltenbrand** (Würzburg) gave a statistical analysis of the occurrence of multiple sclerosis in Central Europe. The incidence appeared to have risen since the beginning of the century. There had, however, been no rise in the number of necropsies in the years immediately after the late war as had been the case after the first world war. In his series the necropsy incidence had varied from 0·73 to 1·6%, the maximum being reached in the year 1936. Constitution, he thought, played an important part. Tuberculosis, syphilis, and rheumatism were more commonly found in subjects with multiple sclerosis than in the general population, while arteriosclerosis was a little rarer and malignancy considerably rarer.

F. **Lüthy** (Zürich) was highly critical of Hallevorden's deductions. We had no proof that multiple sclerosis, diffuse sclerosis, and concentric sclerosis were the same disease. Why then had he paid so much attention to concentric sclerosis, which was admittedly extremely rare? The analogy with ringspot disease was purely superficial. No antibody had been demonstrated in multiple sclerosis.

O. T. **Bailey** (Indianapolis) had studied a case of multiple sclerosis in which the plaque concerned was only eleven days old; his findings were the same as those of Greenfield. Experimental methods were justified if they contributed to knowledge of the formation and maintenance of the myelin-sheath. This was more important than trying to read into them an identity with human demyelinating diseases.

C. **Davison** (New York) was certain that processes of demyelination, which could never be attributed to a single specific factor, were governed by both qualitative and quantitative factors; while A. **Ferraro** (New York) put in a plea that we should not dismiss experimental work as being something too far apart from the human diseases. He was opposed to evaluating either human or experimental material simply on a pathological picture. One must define as clearly as possible the clinicopathological features of each demyelinating disease.

W. **Blackwood** (London) described evidence that the globoid cells in multilocular cerebral sclerosis were of microglial origin and that they contained a non-lipid material of uncertain nature.

L. **van Bogaert** (Antwerp) and J. **Bertrand** (Paris) summed up the discussion. The cellular infiltration sometimes seen in the lesions of multiple sclerosis was only symptomatic; the primary disease was in the myelin. They admitted, with Hallevorden, that there was a myelinolytic substance, but could not agree that the analogy between tobacco mosaic and concentric sclerosis permitted one to postulate a viral origin for Balo's disease and still less for multiple sclerosis. Concentric patterns were to be found in many physicochemical phenomena, including the aurora borealis, but did not argue in favour of a virus. They doubted if there was yet sufficient evidence to place perivenous encephalomyelitis with the allergic disorders. Allergic reactions in the brain were hardly comparable with those elsewhere in the body, for fibrinoid necrosis of the vessels of the brain could be observed in purely toxic states such as carbon monoxide poisoning. They recognised that for the proper understanding of the demyelinating diseases further clinical and biochemical observations were necessary; but they believed that histology, far from having exhausted its usefulness, could still yield much information.

VASCULAR DISORDERS OF THE BRAIN

J. H. **Globus** (New York) discussed the ætiology of massive cerebral hæmorrhage. His hypothesis was an elaboration of that originally proposed by Rouchoux (1844), who held that bleeding was the indirect result of a diseased blood-vessel which first gave rise to an area of softening into which bleeding occurred. Durant-Fraidel (1842) also had this idea of an area of diminished resistance of the brain substance into which bleeding took place. Globus and Strauss in 1927 set out the stages in which a massive hæmorrhage developed, and now there was experimental work to support these observations originally made on clinical material. Infarction had been produced surgically in animals, and hæmorrhages produced afterwards spontaneously or by means of the intravenous administration of arsenical compounds. Evidently several factors were concerned in the causation of a hæmorrhage, but it seemed likely that conditions favourable to bleeding were brought about when a small vessel traversed an area of softening; a naked vessel in this way would be temperamental and liable to give way if the intravascular tension was increased.

W. SCHOLZ (Munich) discussed the changes in the parenchyma of the brain when the vessels were subjected to oxygen deprivation, and showed many examples both in the early stages of nerve-cell damage and in the reactionary stages of neuronophagia and gliosis. He referred at length to the vulnerability of the various forms of nerve-cells and adduced evidence that it was determined in part by the vascular supply of the area concerned, and in part by the peculiar metabolic requirements of the particular nerve-cells. A variety of gross pathological findings might result from oxygen deprivation. His thesis permitted of a reconciliation between the opposing views of Spielmeyer (who held that nerve-cell damage was the result of a local impairment of blood-supply) and of the Vogts (who believed in the theory of pathoclisis). He recognised a difference between simple oxygen deprivation and cerebral oligæmia; in the former the circulation was maintained and metabolites could be removed, while in the latter this was not so.

R. D. ADAMS and J. J. MICHELSEN (Boston, Mass.) contributed a classification of inflammatory lesions of the cerebral blood-vessels. Endarteritis could now no longer be regarded as specific for syphilis; for it was found also in tuberculous and other forms of meningitis, while the smaller vessels had now been shown to be involved, giving rise to a picture which Nesil and Alzheimer would have regarded as specific of syphilis, in such varying diseases as anthrax, glanders, schistosomiasis, and those caused by rickettsiæ. The disorder which we knew as polyarteritis nodosa represented the *end-stage of a variety of different conditions.*

K. T. NEUBUERGER (Denver) evaluated the histopathology of vascular disorders of the brain. Too much emphasis had in the past been placed on vasospasm. In his opinion vasoparalysis, stasis, and peristasis were more important. He did not think it possible or advisable to make a strict separation between functional and organic disorders of the blood-vessels. It was important to establish whether or not a change was reversible. We tended, too, to overlook the importance of the venous circulation; interference with this was often responsible for red softenings.

HISTOPATHOLOGY OF SCHIZOPHRENIA

J. L'HERMITTE, P. GUIRAUD, and L. MARCHAND (Paris) admitted that confusion existed because patients with schizophrenia-like disorders had been found at necropsy to have histological changes which we associated with other diseases. The same had been said years ago of general paralysis, but now we knew that this was a specific disease and that it could be simulated by others. They believed that schizophrenia was an organic disease of the brain.

W. L. BRUETSCH (Indianapolis) dealt with those cases in which demyelination or changes associated with rheumatic arteritis had been found; while C. and O. VOGT (Neustadt) believed that a cell loss occurred in schizophrenia, but that the symptoms were to be attributed to the behaviour of the cells which survived.

D. BOLSI (Turin) and V. M. BUSCAINO (Naples) both dealt with the extraneural pathology of schizophrenia, and L. VAN DEN HORST (Amsterdam) compared the findings in schizophrenia and in schizophrenia-like disorders.

G. PETERS (Bonn) did not believe that schizophrenia had yet been established as a disease entity. It was a syndrome which could be caused by different ætiological factors. This view was supported by L. BINI (Rome) who, on behalf of Professor Marchiafava, demonstrated a case clinically diagnosed as schizophrenia which turned out to be one of rheumatic encephalitis. Other speakers agreed that there was no constant histological pattern, and that when changes did occur they were due to accompanying psychosomatic states, to convulsive therapy, or to terminal diseases. Experts usually could not distinguish the brains of schizophrenics from those of patients who had died of other diseases. One speaker, who held that schizophrenia represented a plurality of syndromes, urged that further clinical analysis was necessary. Simple syndromes, he said, facilitate research.

The difficult task of summing up was left to A. MEYER (London). We had to agree that many cases of schizophrenia showed few lesions, and we had the paradox that the most classical cases were those that showed the minimal change. Even after leucotomy brains had been found to be normal. He hoped that the references which had been made to histological lesions attributable to convulsive therapy would not discredit a treatment of proved value. Secondary changes in the brains of schizophrenics could be due to so many associated disorders—of the autonomic system, for instance, and even liver damage. He hoped that those who favoured a somatic rather than a psychosomatic origin for the disease would not feel defeated. There would always be a somatic factor in schizophrenia. In the course of his communication Professor Meyer described the necropsy findings in twenty-six cases of schizophrenia and in sixteen cases in which biopsy had been carried out. He confirmed not only the essentially negative findings but also the ease with which other diseases could be diagnosed as schizophrenic.

HISTOPATHOLOGY OF MENTAL DEFICIENCY

C. E. BENDA (Waverley, Mass.) described a series of mentally deficient patients. Of these 35% were mongols; in 24% the cause was circulatory disorder, including cystic degeneration of the white matter, subcortical encephalomalacia and cortical atrophy, and status marmoratus. In 14% the cause was infection, mostly postnatal but sometimes occurring during the period of gestation; occasionally mental deficiency resulted from disease of the mother (rubella). Disorders of metabolism accounted for 7% and neoplastic malformation for 5%. The remaining 15% he styled true oligophrenia or oligoencephaly: these were the imbeciles who showed only minor structural abnormalities in the brain.

M. MINKOWSKI (Zürich) confined his remarks mostly to mental deficiency caused by prenatal factors and demonstrated material collected by Monakow and his pupils. W. E. MAFFEI (Sao Paulo) discussed nutrition in relation to mental deficiency; while K. INGLIS (Sydney) reviewed the various forms of extraneural pathology associated with it.

G. A. JERVIS (New York) directed attention to the metabolic causes of mental deficiency. Wilson's disease he believed to be due to an error of amino-acid metabolism, and therefore it fell into the same category as phenylpyruvic oligophrenia. Galactosuria and glycogenosis might both give rise to disease of the brain. All the metabolic disorders had in common their genetic behaviour, which was in accord with a recessive gene. The number of observed cases in families of several forms of metabolic disease of the brain had been in striking agreement with the number to be expected on the basis of a single recessive gene. He believed that one was born with a particular biochemical individuality, just as one was born with a certain physical and psychological personality.

G. de Morsier (Geneva) discussed the causation of agenesis of the corpus callosum and of various forms of cerebral agenesis and hemiatrophy on the basis of vascular lesions. W. G. P. Mair (London) described the findings in seventeen cases of cerebral hemiatrophy; the condition probably dated from birth or from early postnatal life. R. M. Norman (Bristol) described two cases of cystic degeneration of the brain which were undoubtedly prenatal in onset. The first was a twin, the other child having been dead for about ten days before birth. Death occurred at the age of one year and ten months, and confluent cystic cavitation of the white matter was found. Possibly strangulation of the cord had accounted for the death of the one and for encephalomalacia in the other. The second case lived for one month although the mother had had severe transfusion reactions superimposed on profound anæmia. The anoxic origin in both these cases could hardly be doubted.

C. Berlucchi (Pavia) described recent experimental work carried out in his department on toxoplasmosis. N. Malamud (San Francisco) agreed with Benda that some diseases were genetically determined while others were of prenatal origin. But a pathologist found it impossible to say whether a disease was due to birth trauma or anoxia on the one hand, or to some infection in early postnatal life.

SENILE PSYCHOSES

F. Bonfiglio (Rome) said that we had no true knowledge of the causation of senile plaques and of the neurofibrillary change of Alzheimer. These were not found in ageing animals and were not constant in old age in man. Senile dementia had been regarded as an accentuation of normal decay of the brain; but mental decay could not be regarded as physiological in old age, because many never showed it. One could only conclude that factors, be they endogenous or exogenous, other than the process of normal senile involution were necessary for the production of these characteristic lesions. There was, however, an obvious identity between the pathological picture in Alzheimer's disease and senile dementia; in fact an experienced pathologist would find it difficult to distinguish between them. He did not agree with Grünthal that Alzheimer's disease was heredofamilial. He had found no such evidence in some hundred cases of which he had knowledge. In spite, however, of the histological similarity he believed Alzheimer's disease to be different from senile dementia.

P. Divry (Liège) gave a detailed study of the plaques and neurofibrillary alterations, enumerating the varieties of the former which he had encountered. Histochemical analysis showed that they were largely caused by the appearance of amyloid which had precipitated out of the interstitial colloidal medium of the brain. The characteristic changes of Alzheimer's disease could be designated, he thought, disseminated paramyloidosis of the brain.

F. Morel and E. Wildi (Geneva) described further evidence of the histochemical nature of the lesions. The amyloid substance, in their opinion, emanated from the capillaries, or from the capillaries and arterioles; in the former instance one found senile plaques, in the latter instance senile plaques together with the perivascular deposits which they termed, as a pathological process, dyshoric angiopathy.

H. Spatz (Giessen) suggested that Pick's disease was a system disorder; and he classified it in the same main group as cerebral and spinal progressive systemic atrophies along with amyotrophic lateral sclerosis, the various heredo-ataxias, Huntington's chorea, Parkinson's disease, and Leber's primary optic atrophy. At times the disease was widespread, but it was never generalised. The postcentral gyrus, the paracentral lobule, the occipital lobe, the auditory field, and the caudal part of the superior temporal gyrus were usually spared. The affected parts, in fact, were those which were the last to be myelinated. He agreed with Hallevorden that the disease had its origin in the periphery of the neurone.

R. Estrada and F. Fusté (Havana) believed that senile plaques had their origin in degenerating neurofibrillary elements, and that the amyloid and other deposits were the result of this degeneration. They had noticed in patients with senile dementia that when the blood-pressure was low they tended to be not so well.

J. de Ajuraguerra (Paris) believed that in the group of presenile dementias we had to look for factors capable of activating the involutionary process to which all were subject. Circulatory dysfunction, rather than arteriosclerosis, should be looked for in the ætiology of these diseases. This approach was recommended also by C. M. Fisher (Montreal), who described cases of dementia in associating with occlusion of the carotid arteries.

H. Jacob (Hamburg) confined his remarks mostly to the Jacob-Creutzfeld disease; while W. H. McMenemey (London) dealt with the heredofamilial element in the presenile dementias. E. Grünthal (Berne) and W. J. C. Verhaart (Amsterdam) were both of the opinion that Professor Spatz's classification of the progressive cerebrospinal systemic atrophies was rather oversimplified; there were many facts which could not be entirely explained by his hypothesis of degeneration at the periphery of the neurone.

L. Bini (Rome) referred to the reported cases which appeared to be something between Pick's disease and Alzheimer's disease. J. Solé-Sagarra (Barcelona) described new work on Parkinson's disease and compared it with Huntington's chorea. It was left to G. R. Lafora (Madrid) to sum up, which he did with a masterly review of the present position with regard to this group of diseases.

Public Health

Paratyphoid-B Fever in Cardiff

There have been 54 cases of paratyphoid-B infection in Cardiff since the epidemic in South Wales began in the early part of May.[1] In the rest of the South Wales area the total is now approximately 400.

Dr. W. Powell Phillips, deputy medical officer of health for Cardiff, writes:

> "The epidemic has shown that it is relatively simple to trace the immediate vehicle of infection when there is a group of cases whose incubation periods roughly correspond. For instance, in the area there have been 10 or 12 bakehouses involved. Commonly a mild case or a symptomless excretor is discovered at the bakehouse, and that particular source of trouble is eradicated. What remains to be discovered is how the infection gets into the bakehouse and the source of infection among the staff. Naturally all common products, their origin, and method of handling and distribution have been studied. Bacteriological investigations have so far failed to give the answer. On the other hand it is too much to expect that a chance infection has occurred in bakery staffs when such a number of separate undertakings are involved and when there are considerable distances between the various establishments."
>
> "We are now having to deal with cases which are being diagnosed at irregular intervals, and on investigation it is now rare to find any common factor. A certain number of these cases are probably secondary infections, but the continuing incidence gives rise to concern because it is possible that there is some source of infection which is from time to time being distributed outside the city and causing the more localised outbreaks with a common incubation period in the surrounding districts. In other words the infection has tended to persist sporadically in the city since May, whereas elsewhere there have been groups of cases occurring together in districts some distance apart."

In England Now

A Running Commentary by Peripatetic Correspondents

THOSE of us who have not yet been to the regions of heat hyperpyrexia and thermogenic anhydrosis are, I suppose, in no position to criticise the recent D.T.M. & H. papers; but one cannot help regretting all the valuable information that has proved, in the end, of no avail. The questions, if I may say so, seemed very ill designed to elicit a number of important facts—for example, that Pruner's hedgehog in the Sudan is particularly susceptible to yellow fever; that if the housefly bred unchecked it would, in a year, cover the whole Earth's surface to a depth of 47 ft.; that tsetse flies can be collected by drawing a baby crocodile on a small cart through the fly belts; and that not only humans but also carnations are susceptible to sporotrichosis.

* * *

Since leaving school my pooled store of words from the Latin languages has been limited. It was, therefore, with some relief that I reached the house of my friend in Paris. He, however, had not yet come in, and his wife, who was preparing the meal, left me in the sitting-room exposed to the tender mercies of their oldest toddler. Shoving his picture book under my nose, "Qu'est-ce-que c'est?" he crowed, with the delight of the born examiner, who senses that the examinee is on *terra incognita*. "C'est un bœuf," I ventured. "Non, une vache," he corrected. And to make sure that I, at least, derived some profit from the experience he added: "Elle donne le lait." So it went on. I failed to identify the "wolf," whom I called "un reynard." For the world I could not remember the French for "monkey" or "elephant's trunk," though I managed to score with "cheval." When my hostess at last rescued me I was glad to talk again in coherent sentences. Before long, however, the youngster, like an examiner prematurely deprived of his prey, staged a comeback. Tugging at my sleeve, annoyed that now he was left guessing, he cried: "Parlez français, parlez FRANÇAIS!" And to make it clear how reprehensible my conduct was he held forth with irrefutable Gallic logic: "En France on parle français, en Angleterre on parle anglais, et en Chine—en Chine . . ." he halted momentarily, but not for long, for the solution was obvious: "en Chine on parle jaune!"

* * *

Dog-owners are seldom at a conversational loss, and a chance encounter I had the other day with a middle-aged Norwegian medical cynophil lasted about an hour—the first ten minutes being devoted, rather perfunctorily, to shop, and the rest of the hour to a monologue (his, not mine) on his dog. It must have been of a ripe old age, for its saga began in the spring of 1940 when it was part of a small expeditionary force sent by the French Army to the West coast of Norway to remove the Germans. But it was the French who had to evacuate Norway; and the dog was left behind, very much in the lurch, the only attention paid it at first being a charge of buckshot still lodged in one of its legs. Fortunately it found a good friend, and dog and doctor soon became inseparable. Indeed, after they settled in the suburbs of Oslo the dog would meet the doctor every evening when his bus deposited him some way from his house. But one evening its reception of him was as cold and aloof as it had usually been warm and friendly: all its attention was focused on plants and trees and little birds, while Master was icily ignored. At first puzzled and hurt, he could not understand the cause of this sudden estrangement, till he remembered that, a few moments earlier, on stepping off the bus, he had exchanged friendly greetings with another dog, an arch enemy of his own dog.

* * *

It has been said that a man may be described in three ways—as he supposes himself to be, as he appears to others, and as he really is. The third of these descriptions may surely be dismissed; for who is entitled to decide what a person really is? As for the other two, reconciliation is difficult, perhaps impossible. Nobody can take simultaneously a subjective and objective view of anything, and perhaps this is just as well. There may be a few who indulge in the self-depreciation of Robin Oakapple in *Ruddigore*, who protested that people had no idea of what a poor opinion he had of himself and how little he deserved it. The majority are happy in their fool's paradise, and it is cruel to disturb them.

I have been inveigled into this somewhat pessimistic philosophy by the experience of hearing my own recorded voice after a broadcast. I was horrified. I had hitherto plumed myself on the possession of an attractive, cultured, nicely modulated, musical timbre; and I was confronted with a monotonous, nasal, uncouth declamation, the sole recommendation of which was that it was audible.

I am told that everybody, on hearing his voice reproduced for the first time, is surprised and perturbed. That, to a certain extent, is comforting, for the element of instrumental distortion can be invoked. But the fact that those who heard my broadcast, while complimenting me with the observation that it came over well, invariably added that it was a perfectly true reproduction compels me to abandon this consolation. It would have been better to have been left undisturbed in my illusion. And this, I feel sure, applies to a good many other conditions, particulars, and attributes besides the sound of one's voice.

Notice in a New York florist's window: All Our Flowers Contain Chlorophyll.

* * *

He was a foundry-worker aged 68 who had been admitted to hospital some months ago with a severe coronary thrombosis. When I saw him again after a period of convalescence he had done well and I referred him to the almoner in the hope that she would find lighter employment for him. In a brief note she replied that she'd do what she could but his age made it rather a problem. Later she wrote that his wife, very sensibly, had persuaded him to retire completely.

At the clinic today he looked spruce and remarkably fit and happy. "How do you occupy yourself these days?" I asked. His face lit up. "You'll remember, doc," he said, "I was an acrobat before I went to the foundry. I do handstands and jump from table to table." I suppose I looked surprised. "A chap's got to keep fit," he explained.

* * *

A clinical colleague of mine lately came upon a number of old examination papers lying on my desk. Unfortunately the internal evidence was too strong for me to disclaim authorship, and knowing his incisive scorn of the more academic aspects of medicine I expected unflattering comment. However, his love of English outran his reaction to unclinical science—and also his experience of examining. "What do you mean by 'indicate'?" he asked. "Oh," I said airily, "I meant 'I am tired of saying 'describe,' 'discuss,' 'give an account of,' 'state,' and 'mention,' but you can jolly well answer the question in the usual way all the same!'" This didn't satisfy him, and he pointed an accusing (second) finger at me and thundered "Indicate: to point with the index finger. How do you expect your candidates to do that in their written paper?" I have since consulted my dictionary, which does not support him; but at the time I fell for the authoritarianism of the born clinician and turned to musing on the possibilities of using other fingers. Annulate? Minimate? Mediate, forsooth. I set out wearily for home, and, as the buses were full, I felt I should have done better to have pollicated a lift.

* * *

Midwife: "You go and bath the baby while I wash Mother."

Student (several minutes later, with ashen face): "For God's sake come quickly. I've dropped it in the bath."

Midwife: "Well take it out."

Student: "I can't, the water's too hot."

Letters to the Editor

ISONIAZID

SIR,—Strains of tubercle bacilli insensitive to isoniazid have been isolated from the sputum of tuberculous patients before, during, and after therapy with the drug.[1] It seems that isoniazid-resistant bacilli may become more numerous after about 8 to 12 weeks' treatment.[2] Since the appearance of drug-resistant bacilli foretells the loss of effectiveness when other drugs, notably streptomycin, are given, some clinicians have expressed doubts as to the efficacy of isoniazid.

We believe that the phenomenon of drug resistance should not be used as the chief criterion of a drug's value. The real evaluation must always depend upon clinical tests of efficacy. By this criterion, isoniazid has not failed.

The most rapid and definitive clinical test of an anti-tuberculous drug is its use in treating miliary and meningeal tuberculosis.[3] Isoniazid is proving at least as effective as streptomycin in controlling miliary disease.[4] Results in other forms of tuberculosis are generally satisfactory so far as can be judged at present, and it is suggested that no adverse conclusions can be drawn until the current extensive clinical trials are completed.

The phenomenon of isoniazid resistance is of great theoretical and practical interest particularly because it may not be exactly analogous to bacterial resistance to other drugs. In the early investigations at the Squibb Institute for Medical Research, *Mycobacterium tuberculosis* easily became resistant to isoniazid, and subsequent reports have confirmed this observation. Resistant strains appear in vitro after prolonged culturing of a single inoculum in the presence of isoniazid,[5–7] and after repeated subculturing in increasing concentrations of the drug[8]; iproniazid, the isopropyl derivative, gives similar results. In general, isoniazid-resistant strains are difficult to maintain in culture, which probably indicates greatly increased metabolic requirements,[9] in contrast to the characteristics of streptomycin-resistant strains. Further, isoniazid-resistant, but not streptomycin-resistant, strains may again become sensitive when cultured in media not containing the drug.[10] Although some strains resistant to isoniazid in vitro are also resistant to the drug in vivo,[11] at least some of the resistant organisms have lost their virulence. These observations may explain why no-one has yet demonstrated a close and consistent correlation between the appearance of isoniazid resistance and clinical relapse. They raise the question as to what observed changes in the isoniazid sensitivity of tubercle bacilli are of significance to the clinician treating tuberculous patients.

While this question will be answered in time, the clinician cannot wait to plan treatment for his present patients. Several considerations can guide him in his decisions. No cross-resistance exists between isoniazid and the streptomycin drugs, *p*-aminosalicylic acid (P.A.S.), or amithiozone,[12–14] and it has been shown in vitro that no tubercle bacilli resistant to either agent emerge when cultures are exposed simultaneously to isoniazid and streptomycin[10, 15]; admixture of these two agents also appears to potentiate their antibacterial action.[16] It was suggested at the recent annual conference of the British Tuberculosis Association[2] and elsewhere[5–7] that isoniazid be used with streptomycin. We have received personal communications about the treatment of more than 500 patients with a combination of isoniazid and one of the streptomycin drugs, and the safety of this combination has been demonstrated.

We have always regarded isoniazid as a valuable new therapeutic adjunct rather than as a complete cure for tuberculosis. Obviously we do not yet know how isoniazid can be used most effectively; some five years were needed to find and test the presently accepted streptomycin régimes. We can, however, use our experience with streptomycin and P.A.S. to guide us in administering isoniazid until more definite information is available. At present it would appear that isoniazid should usually be given in daily doses of 3 to 5 mg. per kg. body-weight by mouth, with streptomycin in intramuscular doses of 1 to 2 g. twice weekly, but only as a part of the complete treatment which includes bed rest and surgical care. The truly threatening forms of tuberculosis, such as miliary, meningeal, and extensive pneumonic disease, probably should be treated more vigorously with larger doses of both drugs; and perhaps with P.A.S. as well.

The results so far available indicate that combined treatment with isoniazid and streptomycin is likely to prove superior to older methods of treatment. Our present lack of information only emphasises the need to continue the orderly search for the best isoniazid régime. Until this search is ended, the profession must reserve judgment on the ultimate value of isoniazid. We must remember that streptomycin, now regarded as the standard of comparison for other antituberculous drugs, was itself treated with reserve until the current methods of use were evolved.

STATUS IN THE SERVICES

SIR,—It has come to our notice that officers fulfilling their National Service obligations are occasionally appointed to posts that carry a specified rank and rate of remuneration which are denied to them by the central authorities concerned. They have perforce to seek the assistance of professional organisations to establish their rights in this matter, though these rights are patent to anyone who is familiar with establishment of the units concerned. Already in three instances solicitors have been instructed to make representations to central authorities to observe their own rules and regulations by conceding the higher rank to which the medical practitioner is entitled and making payment of remuneration on the enhanced scale.

Medical officers who fail to receive the acknowledgment of rank and pay to which they are entitled should communicate with their professional organisations as soon as practicable to enable representations to be made on their behalf before valuable time has been lost and tempers have been ruffled. That this intervention should be necessary is deplorable since the authorities concerned ought to be anxious to observe their regulations, at any rate to such an extent as to prevent any medical officer from suffering loss of status or remuneration to which he is clearly entitled.

It is hoped that medical officers will not accept these indignities with complaisance, and that they will not

HÆMOPHILIOMETER

SIR,—The techniques for diagnosing the presence of hæmophilia seem to be getting more reliable, but there remains a crying need for a simple, reliable, and harmless means of determining the "degree" of hæmophilia at any given time.

It does not seem to be fully realised that, whilst the hæmophilic is "constantly" hæmophilic, the extent of the hæmorrhagic diathesis may vary widely, sometimes slowly over a long period of time but sometimes rapidly in a matter of hours. The lack of any reliable means of determining the patient's hæmophilic state at any given time imposes a great strain on patient and doctor alike.

A "Hæmophiliometer" is therefore very urgently needed, and I appeal to research-workers to give this problem their attention.

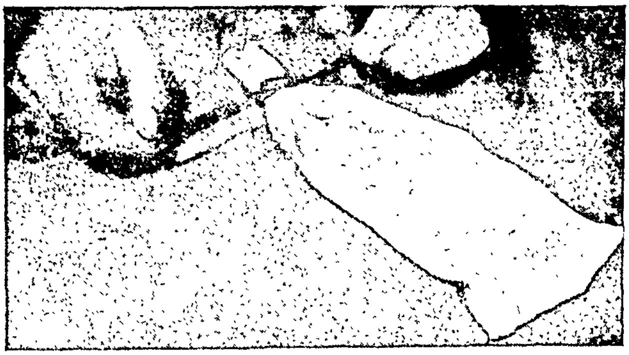
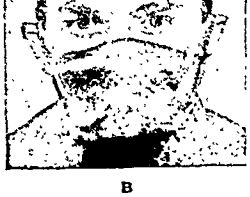
A CHEAP SURGEONS' CAP

SIR,—For the surgeon who is operating there are many models of headwear, most of which are secured by tape. They are made from various materials, some expensive; and hospital seamstresses and commercial firms spend a lot of time on the intricate suturing. The end-result is a sweaty rag which constricts the venous return of the scalp, gives the surgeon a headache, and commonly slips out of place. Surgeons, being by nature ingenious, overcome these difficulties by their pet modification, such as a sweat band round the forehead.



A

During and since the late war I have used for operating a hat which takes less than thirty seconds to make, cannot cost more than a few farthings, is light and comfortable, absorbs the sweat, and stays in position. It is made by cutting a short length (about 12 in.) of orthopædic stockinette, of suitable diameter according to the size of the head; a knot is tied in one end with a piece of string to make a small pom-pom (fig. A), and the hat is then ready for use (fig. B). Theatre sisters can exhibit their artistry and regard for their surgeons by embroidering the lower edge of the hat, if they wish; but this is unnecessary as the stockinette can be rolled up to form a natural hem and, incidentally, a sweat band.



B

I heartily commend this hat, for which I claim no originality whatever, although I have never seen it used anywhere else. It would save the Ministry of Health a lot of money, time, and labour; and its comfort would save many surgeons headache and fatigue which inevitably lead to ruffled tempers.

I am grateful to the photographic department of St. Bartholomew's Hospital for the photographs.

St. Bartholomew's Hospital,
London, E.C.1.
JOHN HOWKINS.

CURE OF TOBACCO-SMOKING

SIR,—It is remarkable that no reference has so far been made to the silver nitrate cure.

The method is simple and inexpensive. Immediately after meals the smoker strokes the tongue two or three times with a stick of silver nitrate and then rubs the tongue against the palate and buccal mucosa for half a minute or so. Thereafter he finds that the taste of tobacco-smoke and silver nitrate combined is so peculiar that he derives no pleasure from smoking. If this procedure is carried out for, say, three consecutive days, the smoker who is really in earnest about his cure finds it much easier to abstain. The treatment should not be continued for more than three days because of the risk of argyria from the prolonged use of silver salts.

What matters most is the attitude of the smoker. I have recommended the treatment to many of my friends, and I am able to report that without exception they have given up the silver nitrate. *Vouloir c'est pouvoir.*

Department of Materia
Medica and Therapeutics,
The University, Glasgow.
STANLEY ALSTEAD.

SIR,—Dr. Lennox Johnston has avoided the main difficulty confronting most heavy smokers—namely, how to give up smoking without admitting that it is a habit, and possibly a bad one, and so losing face. To make an oath of total and everlasting abstention is a terrible thing for any man to do. But there is a way out of his dilemma. Let him vow only to smoke tobacco that he has grown and cured himself. His own cure is then certain and, if he is married, rapid.

Upton on Severn,
Worcestershire.
H. F. GREEN.

SIR,—My critics (Sept. 13) do not appear to have grasped my most fundamental point—that tobacco-smoking is not a habit but a specific infectious disease. Like other drug addictions, it is an intermittent intoxication, and habit and vice are incidental.

I do not agree with Dr. E. C. Cordeaux that smoking is easy to stop. Even with medical assistance, supported by strong economic pressure, I estimate that less than half of those who try to stop smoking succeed. Difficulty varies with the strength of acquired craving for tobacco, and inversely with the strength of resolution to stop.

I agree with Dr. Gordon Ambrose that some smokers can be cured by suggestion; but unless suggestion is supplemented by undeception and re-education, relapse is extremely probable. I also agree with most of Dr. Ellis Stungo's observations; but is not auto-suggestion on the lines he indicates in fact auto-analysis, a procedure which clarifies knowledge about smoking and which brings with it resolution to abstain?

I shall take Dr. Christopher Howard's criticisms (Sept. 20) seriatim. The immediate soothing (and *apparently* beneficent) effects of smoking on smokers are not disputed. Nor are the soothing effects of smoking other drugs—e.g., marihuana and opium—but these soothing effects are inevitably followed by toxic after-effects.

umber of cured smokers interviewed.—Scarcely a smoking ient has consulted me during the past 24 years who has been subjected to a harangue (!) on the ill effects of smoking te "ill effects," not "evils," for this is a medical, not a al, issue). As my proficiency in presenting the case against acco, and in refuting arguments in favour, has increased, as evidence in support of my views has accumulated, my portion of cures has increased. An average of 10 cured kers per week—although not necessarily permanently ed—during the past 24 years is not, I consider, an overimate.

etoxication.—It is surely justifiable to assume that when individual ceases to take a toxic drug, such as nicotine, oxication and consequent improvement in health begin once.

efinite proof that cancer of the lung is related to smoking.—ll and Bradford Hill[1] discuss the possibility that improved gnosis might account for the great increase in deaths from cer of lung, and conclude that "there is sufficient evidence reject that factor as the whole explanation, although no one ld deny that it may well have been contributory."

rsenic.—I merely mentioned its occurrence in tobacco oke. Dixon[2] wrote: "Arsenic is a constituent of American baccos in amounts many times greater than those permitted foods."

Wallasey, Cheshire. LENNOX JOHNSTON.

EMPLOYMENT OF REGISTRARS

SIR,—Dr. James Fairley, Deputy Senior Administ ative Medical Officer of the South-East Metropolitan egional Hospital Board, said in his letter last week at he was "directed" to state that candidates for nior registrarships are not required to have held a gistrar appointment at a teaching hospital for two ears, but that preference is given to applicants who ave had such experience.

Will Dr. Fairley's assurance comfort Mr. Thomas and is colleagues in the Bromley group (and their anxiety bout the future registrar position is common to all on-teaching groups)? To a potential applicant for a egistrarship in a non-teaching hospital it would appear o be as reassuring as the paratroop instructor's reply o the inquiry "what do I do if the parachute don't pen, sarg.?": "Don't worry, son, we gives you a ew one—free!"

The problem could be solved practically by making ll registrarships below the senior grade joint appointnents between the teaching hospitals and the regionaloard hospitals. A tour of duty by a registrar in the ospitals of the region would be of great benefit to all oncerned, not least to the registrar himself.

South Shields. TERENCE G. ROBINSON.

FRESH BLOOD

SIR,—My committee have been told that the medical taff in some hospitals are under the impression that the reater London Red Cross Blood Transfusion Service as ceased to function. I can assure you that this is not so, and that to the end of last July the service had nswered 74,000 calls. May I take this opportunity of explaining the functions of the service?

It is the oldest organised blood-transfusion service in the world, having been inaugurated in 1921 by the late Percy Oliver. When the National Health Service came into operation this Red Cross service was requested by the Ministry of Health to continue its work of providing voluntary blood donors to hospitals in the Greater London region for cases where freshly drawn blood was considered essential or preferable. To meet the administrative costs a per-capita payment of one guinea was agreed, but at the request of my committee this was reduced to 16*s*. in January, 1951.

The members of the service are medically examined on enrolment, and their blood is tested and grouped by the medical officer of the service, Dr. H. F. Brewer, of the pathological department of St. Bartholomew's Hospital, where they are also grouped for the Rh factor.

The service is a day-and-night one. A telephone call to Stamford Hill 0091 will receive immediate attention, and donors of the group or groups required will at once be supplied. Donors are also supplied for hospitals and nursing-homes outside the National Health Service at a minimum donation to the funds of one guinea, and a number of these calls are received each year.

Greater London Red Cross Blood
Transfusion Service,
324, Seven Sisters Road, N.4.

A. W. PILGRIM
Chairman.

SORE THROAT AND RHEUMATIC FEVER

SIR,—With reference to the letter from Dr. Stewart and Mr. Hewitt (July 19), there is an important point not generally taken into consideration when statistics are studied.

At one time I was an "onlooker" at an investigation into the incidence of upper respiratory tract infections in (*a*) children who had had the tonsils and adenoids removed and (*b*) those who had not.

The investigator's method was to ask each child: "Have you had your tonsils and adenoids removed?" No examination was made. Of twelve of the children who had answered "yes" and whom I was able to examine later, all had tonsillar tissue in the fauces—in two or three it was almost impossible to detect that tonsillectomy had ever been performed. In several of the children with whom posterior rhinoscopy was possible, quite large pads of adenoid tissue were also noted. These children, however, were rated as having had the tonsils and adenoids removed.

One would suggest, therefore, that when tonsillectomised and other children are to be compared for any purpose, those who are found still to have tonsillar tissue in the fauces or nasopharynx should not be included in the investigation as having had the tonsils and adenoids removed. Obviously the children should be examined by an experienced person.

Australia.

HERBERT EARNSHAW.

SUCCINYLCHOLINE

SIR,—Following the excellent contributions of Dr. Bourne[1] and Dr. Evans[2] and their colleagues, a number of cases of delayed recovery after injection of succinylcholine were reported. In the 2 further cases described here the blood-cholinesterase levels were determined.

CASE 1.—The first patient was an apparently healthy man, aged 60, weighing $9^{1}/_{2}$ st., who was to have radium needles inserted through a fenestration in his thyroid cartilage. He was premedicated with morphine sulphate gr. $^{1}/_{6}$ and atropine sulphate gr. $^{1}/_{100}$, and one hour later anæsthesia was induced with 0·45 g. thiopentone sodium and 75 mg. succinylcholine. A cuffed oral endotracheal tube, lubricated with 1% amethocaine ointment, was easily passed and connected to a semiclosed Boyle's machine delivering nitrous oxide 6 litres per minute and oxygen 2 litres per minute. Apnœa lasted for 75 minutes and respiration was adequate at the end of the operation 5 minutes later. The patient was awake when seen in bed 15 minutes afterwards. Several times during the operation when surgical stimulation was intense (e.g., chiselling thyroid cartilage) "bucking" occurred, but complete respiratory arrest followed withdrawal of the stimulus.

Six days later the patient was given 0·4 g. thiopentone sodium and 25 mg. succinylcholine for removal of the radium. Apnœa lasted 15 minutes and breathing was quite adequate 3 minutes later.

CASE 2.—The second patient was a boy, aged $6^{1}/_{2}$ years, weighing 2 st. 13 lb., who was to have an œsophageal stricture dilated with a Negus bag dilator. Premedication consisted of 'Omnopon' gr. $^{1}/_{8}$ and scopolamine gr. $^{1}/_{375}$ 75 minutes before induction with 0·3 g. thiopentone sodium and 50 mg. succinylcholine. It was 75 minutes before spontaneous respiration returned. "Bucking" occurred when the Negus

2. Dixon, W. E. *Ibid*, 1927, ii, 719.

---

1. Bourne, J. G., Collier, H. O. J. Somers, G. F. *Lancet*, 1952, i, 1225.
2. Evans, F. T., Gray, P. W. S., Lehmann, H., Silk, E. *Ibid*, p. 1229.

dilator was fully inflated, and mucus was aspirated from the lungs on several occasions. Nikethamide 2 ml. and picrotoxin 3 mg. produced no response.

Whole-blood cholinesterase levels in these patients and in five others who responded *normally* to succinylcholine (i.e., about 5 minutes' apnœa) gave the following results:

Case no.	*Response to succinylcholine*	*Cholinesterase**
1	Delayed (75 min. apnœa)	94
2	Delayed (75 min. apnœa)	91
A	Normal	125
B	Normal	115
C	Normal	113
D	Normal	124
E	Normal	114

* The cholinesterase number was determined by the Michel electrometric method,[3] and should be considered with reference to the normal range of 80–129.

The differences in cholinesterase number between patients with normal and those with delayed response are thus not so great as the differences cited by Bourne et al.; but the simplicity of the Michel method makes it very suitable for screening cases in which the use of succinylcholine is proposed. We hope to carry out further work to ascertain whether plasma or erythrocyte levels would show a wider divergence by this technique.

Royal Victoria Hospital,
Belfast.

D. W. NEILL.

AVERSION TO ALCOHOL

SIR,—Dr. Pullar-Strecker refers (Sept. 13) to aversion to alcohol in Hodgkin's disease.

I have suffered from Hodgkin's disease for five years at least. Very early on I became aware that about ten minutes after the ingestion of alcohol I had a pain at the site of the lesion.

I have told this to many doctors, and most of them have, I suspect, thought that it was a psychoneurotic symptom but that I must be humoured. One professor, however, told me that it was a well-known phenomenon and that I must be absolutely teetotal. Another very famous physician said: "Well, alcohol is a vasodilator, so why not?" The radiotherapist who has successfully treated me has found another patient who volunteered the same information; so I am convinced that this is real. The sensation is so unpleasant that I have not persevered in experiments into its cause, but it seems that it might be worth investigating in our search for the cause and cure of this baffling disease.

ANON.

CANADIAN UNIVERSITY APPOINTMENTS

SIR,—I note in your issue of Aug. 16 an advertisement for an assistant or associate professor of anatomy in a Canadian university at $4600 per annum. May I make this the occasion of some general observations on the state of affairs in Canada?

In the first place, your readers should be aware that Canadian *universities* rarely advertise for staff for medical schools, and that almost the only appointments advertised are those which Canadian doctors will not consider because they regard the salary as too low. Canada is the richest country in the Commonwealth and soon will be the richest country in the world. Correspondingly, the cost of living is high, and in the city where this associate professor of anatomy is to live it is higher than in most parts of the United States. My own estimate is that to have the same standard of living as a reader in anatomy in the United Kingdom, an associate professor here would require at least $8000 per annum. Commencing salaries are maximum salaries.

The Canadian medical profession, in my view, ought not to tolerate a situation whereby few (or no) Canadians will accept preclinical posts in their medical schools. And until the Canadian Medical Association lays down a salary scale for all hospital and medical school appointments, intending candidates for Canadian posts should exercise due caution.

Canada.

TEACHER.

ACHALASIA *v.* CARDIOSPASM

SIR,—In the interests of accuracy I should like to point out that Ryle's patient with cardiospasm was not cured by the laying-on of hands. His symptoms were completely relieved and he was able to take part in vigorous athletics, but X-ray examination showed that the dilatation of the œsophagus and the hold-up at the cardia remained unchanged.

The Radcliffe Infirmary,
Oxford.

L. J. WITTS.

WHAT OF GENERAL PRACTICE?

SIR,—It seems a just summary of the discussion in your columns to say that since the demise of unspecialised consultant physicians the G.P. is the only comprehensive doctor left. As such he is the only one with the practical experience necessary to gain an over-all view of medicine.

It would now seem high time he concerned himself with the subjugation of this unruly machinery of hospital and "scientific" medicine to the needs of his patients. That the machine is in part human must be allowed for, but this complication of evolutionary regression, by which a proportion of his colleagues have become cardinals of the machinery, must not distract the G.P.'s attention in his over-all view of the mechanism.

As in all similar modern devices, the man—the whole man—must be master, or nothing but ill will come of it.

London, S.W.10.

B. M. O'SULLIVAN.

SIR,—It has been suggested that a part of my letter of Sept. 20 might be interpreted as a criticism of certain services in this area. If this is so, may I quickly state that the general practitioners of Shropshire are fortunate in having access to an excellent and comprehensive pathological service. It is this happy experience which makes me feel that such an arrangement should be universal, and that it ought to be possible to provide access to X-ray departments in a similar way.

Shrewsbury.

JOHN C. RYLE.

SALT-LOSING NEPHRITIS

SIR,—We are grateful to Dr. McGowan (Sept. 20) for drawing attention to an error in our paper on salt-losing nephritis (Sept. 6). We would point out, however, that the mistake was not one of biochemical estimation. The figures for serum-chlorides given in the table for case 2 actually represent chlorides as sodium chloride and should have been written and calculated as such. Thus the correct milliequivalent values for chlorides in this case lie between 61·0 and 79·0, levels which are quite compatible with the low serum-sodium figures and with a diagnosis of marked salt depletion.

The suggestion of Dr. Atkinson and Dr. Prankerd (Sept. 13) that in 2 of our patients the state of salt loss might have been secondary to tuberculosis is interesting but, we think, untenable. In the first place, as they point out, the cases of Westwater et al. showed *no obvious* renal damage to account for their low serum-sodium levels; our cases, on the other hand, all showed *gross* disorganisation of the kidneys. Secondly, we do not consider that our cases (the one with a small *unilateral* apical lesion and the other with healed miliary disease) are comparable with a *group* of patients who were seriously ill or dying from their pulmonary tuberculosis, for it was among such a group that Westwater *et al.* found the low levels of serum-sodium. Thirdly, no less than 9 out of 24 of their patients who died showed "unequivocal proof of adrenal injury," evidence which was sought but not found in our cases, though the adrenals were not, it is true, actually cultured for tubercle bacilli.

As regards case 1 we had, as we admitted, no biochemical evidence of salt depletion in life. Since the publication of our paper, however, we have received information about the sodium chloride content of the grey matter of the brain tissue in this case. Estimations were performed at the time by Dr. H. G. Close, and he has kindly allowed us to quote his results. In six out of seven specific areas of the patient's brain sodium chloride levels were below average (for between 42 and 71 brains), while in the seventh it was above average. The mean of Dr. Close's values for the seven areas are:

---

[3] Aldridge, W. N., Davies, D. R. *Brit. med. J.* 1952, i, 945.

"Average": 0·286 g. per 100 g. (wet weight) as NaCl.
Case 1: 0·258 g. per 100 g. (wet weight) as NaCl.

We cannot, of course, put forward these figures as confirmation of renal salt loss, but they do suggest that, in this case, salt levels were in fact lowered.

Finally, we agree with your correspondents that in case 3 the diagnosis of salt-losing nephritis was made largely on clinical and therapeutic grounds. But while we would have preferred to have been able to give more biochemical evidence, we do not think the diagnosis is in reasonable doubt because that information is lacking.

Guy's Hospital,
London, S.E.1.

C. L. JOINER.

Medicine and the Law

Responsibility in Hospital

THE Court of Session in Edinburgh has contributed a fresh decision on the important issue of the liability of hospital managements for the negligence (if established) of the surgeons and physicians on their staffs. A woman met with a riding accident and was thrown from her horse in such a way as to sustain a fractured nose and facial abrasions. The wounds were ingrained with dirt and stone particles. Her family doctor applied temporary dressings and sent her, with a note explaining what had happened, to the outpatient department of the hospital. She complained that the two doctors who treated her at the hospital had failed to carry out a thorough surgical cleansing of the wounds and that, in consequence, there was unsightly discoloration of her forehead and nose, permanently spoiling her personal appearance. She claimed £3000 damages from the board of management of the Royal Infirmary at Edinburgh and from the two doctors. The Court of Session dismissed the claim against the board and remitted to a jury the claim against the doctors. The board had contended that, as the doctors were exercising their professional skill in the treatment of the patient, the hospital authorities could not be vicariously liable for any negligence on the part of the doctors. The court upheld this contention. Reference was made to two sections of the National Health Service (Scotland) Act of 1947 which roughly correspond with similar sections in the English Act of 1946. These were sections 12 (dealing with the functions of regional hospital boards and boards of management) and 14 (dealing with the conditions of service and appointment of officers). The latter declares that "All officers employed for the purposes of the functions of a Regional Hospital Board under the Act shall be officers of that Board." The court held that this statutory provision had not displaced the common law of Scotland so as to create the relationship of master and servant between the board of management and the two doctors who treated the patient.

There seems in this respect no reason why the law of Scotland should differ from that of England. The legal position in England, however, has undergone some change since the often quoted case of Hillyer *v.* St. Bartholomew's Hospital in 1909 when it was held that the only duty undertaken by the governors of a public hospital was the duty to use due care and skill in selecting their medical staff. In Smith *v.* Martin and Hull Corporation (1911) Lord Justice Farwell held that the hospital undertakes towards its patients nothing more than the obligation to provide premises where they will be treated by experts; the experts he defined as "surgeons, physicians, or nurses of whose professional competence the governors have taken reasonable care to ensure themselves." "I see no ground," he continued, "for holding . . . that the hospital authority makes itself liable for damages if members of its professional staff . . . act negligently towards the patient in some matter of professional care or skill." The learned judge, it will be noted, placed nurses in the same category as a senior consultant surgeon. Lord Justice Kennedy, whose judgment in Hillyer's case is usually relied upon, conceded that the hospital authority *might* be legally responsible for its servants' acts inside the hospital if the acts were "purely ministerial or administrative"—for example, if a nurse had to summon medical aid in an emergency. Any idea, however, that the hospital authority could always escape liability by regarding its medical staff as independent experts rather than servants was dispelled in 1937 by the decision in Lindsey County Council *v.* Marshall. There the medical officers in charge of a county council's maternity home were alleged to have admitted a mother for her confinement without warning her that there had been a recent case of puerperal fever in the home and that she ran the risk of infection. The county council was held liable to pay damages.

The most important review of Hillyer's case occurred in Gold *v.* Essex County Council in 1942 when Lord Justice Farwell's and Lord Justice Kennedy's opinions were critically examined. A child had suffered facial injury because the radiographer (fully competent, according to the evidence, to do his work) had omitted to provide adequate screening material when giving Grenz-ray treatment. The county council was held responsible. The radiographer was under a contract of service with the council and the doctrine of *respondeat superior* applied. The earlier rulings about nurses were criticised and, although in Evans *v.* Liverpool Corporation consultant physicians and surgeons had been held in 1906 not to be the servants of hospital authorities, Gold's case furnished a dictum that medical practitioners on the permanent staff might be servants of the hospital authority if they had entered into a contract of service. Lord Justice (now Lord Chief Justice) Goddard was unable to see why a hospital should be exempt from liability if a nurse carelessly administered a dose of poison instead of medicine and yet liable if the cook mixed some deleterious substance in the patient's food. Hospitals, he added, employed many specialists—solicitors, accountants, engineers, electricians, and the like; why should a hospital be responsible for those servants' acts and not for those of nurses who were equally in their service? Then came an important passage. "That they are not liable for the doctor's negligence is due simply and solely to the fact that he is not their servant. I desire, however, to say that for the purpose of this judgment I am not considering the case of doctors on the permanent staff of the hospital. Whether the authority would be liable for their negligence depends, in my opinion, on whether there is a contract of service, and that must depend on the facts of any particular case."

On top of all this came the dicta of Lord Justice Denning in Cassidy *v.* Ministry of Health, early in 1951. There the trial judge held that neither the doctor nor any member of the hospital staff had been negligent; the Court of Appeal, however, held that a jury could have found a verdict of negligence as the evidence stood. Lord Justice Denning used language which indicated that a hospital doctor is a hospital employee for whose negligent acts the hospital is legally responsible. If the opinions of the learned Lord Justice have occasionally been overruled by the House of Lords as somewhat too progressive, they are nevertheless entitled to high respect. We must wait for the appropriate set of facts to enable the House of Lords to say the last word on the law as it now stands.

Obituary

ALFRED FRANK TREDGOLD

M.D. Durh., F.R.C.P., F.R.S.E.

BORN in 1870, A. F. Tredgold came of a Cornish family which has latterly had a strong medical tradition. He trained at Durham University College of Medicine and at the London Hospital, where he was a prize-winner in anatomy, biology, physiology, pathology, and medicine. On qualifying in 1899, he was offered a research scholarship, recently founded by the London County Council, for the study of insanity and mental diseases. He chose mental defect as his subject—one little enough studied before that time—and for two years worked in the L.C.C. mental hospitals, and the central laboratory at Claybury Hospital on its causation, pathology, and clinical varieties. He hoped to make the pathology of mental disease his life study, but, as so often happened in those days, he was not in a financial position to follow his bent, and instead he went into general practice. He still kept his clinical interest in mental disease, however, and in 1905 was appointed as a medical investigator to the Royal Commission on the Feeble-Minded. This enabled him to gain additional experience, which helped to form the background of his classical *Textbook of Mental Deficiency*, first published in 1908. This was easily the most comprehensive work on the subject which had ever appeared, and it was warmly welcomed. During the next few years he lectured widely in support of the Mental Deficiency Bill, based on the recommendations of the commission. The Bill was passed in 1913, and by 1914 Tredgold, now an accepted authority on his subject, was able to enter consultant practice in London.

He had been interested in the Volunteer movement for many years, and had been commissioned, in 1905, as a combatant officer in a Volunteer battalion of the Queen's Regiment. In 1914 he was in command of a company, but as doctors were scarce when war broke out he asked the War Office whether they wished him to transfer to the R.A.M.C. Since he was a neurologist and psychiatrist, the War Office of those days was under the impression that his services would not be needed, and he was told to remain as a combatant. A combatant he accordingly remained, seeing service at Gallipoli, as adjutant of his battalion with the rank of major. After Gallipoli was evacuated he served in Egypt and Sinai, until ill health led to his return to England. He was posted to the command of his local Territorial depot until the end of that war.

In 1919 he had leisure, at last, to take the M.D. of Durham University, and in 1921 he became M.R.C.P. His practice as a consultant steadily increased, but he gave up much of his time to committee work, serving on the deficiency committees of the Board of Education and the British Medical Association, the Ministry of Health committee on sterilisation, and many others. He was appointed neurologist to the Royal Surrey County Hospital, and physician in psychological medicine to University College Hospital, and he lectured at Bethlem and the Maudsley Hospitals, and at the London School of Economics. He also instructed a very large number of school medical officers and public authorities in the features of mental defect, lecturing and demonstrating, over many years, to classes of 70–80 graduates, under the auspices of the National Association for Mental Defect. In 1929 he was elected F.R.C.P. He contributed on neurological subjects, and on the clinical and social aspects of mental defect, to many scientific journals. He was invited to give the Galton lecture to the Eugenics Society, and was president of the section of psychiatry of the Royal Society of Medicine. His *Textbook of Mental Deficiency* was regularly revised, and at the time of his death had reached its 8th edition. His *Manual of Psychological Medicine*, first published in 1943, was also widely read.

The death of his wife in 1947, within a year of two of their golden wedding, was a great grief to him; and shortly afterwards he lost the sight of one eye through glaucoma. The gradual failure of sight in the other eye, and a cerebral vascular lesion last year, combined to disable him; but with the help of his son, Dr. Roger Tredgold, he was able to get the new editions of his two books ready for the press. He died on Sept. 17.

E. O. L. writes: "Of very few workers in any field of science can it be said that they initiated a new era. Dr. A. F. Tredgold is one of this select few. Without disparagement of textbooks on mental deficiency written previously, it can be maintained that with the publication of Tredgold's book in 1908 a new era began in this branch of medicine. Earlier textbooks had been mainly descriptive; Tredgold was the first writer to present what was known about mental defect at the beginning of this century as a systematic body of knowledge, with a scientific classification based upon well-defined theories of causation. His extensive and thorough clinical knowledge of mental defectives and his researches in the cognate pathology enabled him to write a book that was lucid, comprehensive, coherent, and in many respects original. For nearly half a century his *Mental Deficiency* has been the standard textbook in this and other countries—surely a unique achievement in medical literature. Moreover, on the day we receive the sad news of his death we find a new edition of his book being placed on the bookstalls: and it is safe to predict that the book will remain the standard work on the subject for several years again.

"A comparison of the eight editions of Tredgold's textbook enables the reader to obtain a fairly complete picture of the progress made in the study of mental deficiency during the last fifty years. Throughout this period, and even in these last few months when over eighty years of age, Tredgold kept himself informed of the work of other investigators; and he incorporated the latest findings, with admirable impartiality, in the successive volumes. He welcomed with zest the researches of others in mental deficiency, and gave their findings most thorough and painstaking consideration. His thoroughness is well exemplified by the way he assimilated each new finding and integrated it with his own views, theories, and teaching. So masterly is this assimilation that the young student who reads the latest edition of the textbook will not be confused by the conflicts that exist in this field of science. Tredgold himself, however, recognised that some recent researches, such as those in genetics, challenged the validity of his theories of causation, and more especially his advocacy of the hypothesis of *blastophoria* or germ corruption.

"Whilst his textbook was Tredgold's chief contribution, he rendered great service to medicine in many other ways. He had been a member of almost every important committee set up by Government departments and voluntary bodies concerned with the welfare of the mentally defective during the last fifty years. In all discussions he held fast to what he regarded as true and sound; but, when other members of the commission or committee held contrary views with equal tenacity, Tredgold always sought a practical compromise. For many years he has been the chief consultant physician in mental deficiency in this country. By his tact and very genuine sympathy, he enabled many parents to orientate themselves rightly to the acceptance of one of the greatest disappointments of life—to the fact that one's child will never be normal mentally. In the course of my official visits, I heard nnumerable spontaneous tributes by many workers mongst those who are mentally handicapped to the eadiness with which Dr. Tredgold invariably responded o requests for guidance and assistance. He was highly ndowed with many talents, and these he invested in he service of those who had but a single talent."

MILLAIS CULPIN

M.D. Lond., F.R.C.S.

Millais Culpin—the Christian name is a family one—was born in 1874, the son of a doctor in general practice in Stoke Newington. His education began at the local school and was continued at the Grocers' Company School where he obtained a scholarship and incidentally acquired his lifelong interest in entomology. Soon after he had matriculated, his father, for health reasons, decided to leave England and set up in practice in Brisbane. Here Millais tried many ways of earning a living, including gold-mining—at which, as he frequently remarked, he had no success. After that experience he travelled to Cape York Peninsula and worked as a schoolmaster for four years. In later life he often referred to this period as a very happy one, and asserted that if the educational authorities had not promoted him to the nearest town, Townsville, he might have remained in his remote post for life. At Townsville he found himself one of a large staff, and this he disliked intensely. So, having saved some money, he returned to England to study medicine. He gained a scholarship at the London Hospital and qualified in 1902. His training here gave him plenty of opportunity for his critical faculties, and he found many current theories of disease causation unsatisfactory. As a student he used to marvel that a celebrated physician or surgeon could make a diagnosis on what to him seemed inadequate data. He found surgery, probably because of its relative objectivity, more satisfying than medicine.

Having qualified, he returned, for family reasons, to Queensland. In 1907 he took his F.R.C.S. and settled in practice in Shanghai, where he was very happy and developed a lasting interest in China and its problems. He married Ethel Maude Bennett and in 1913 decided to return home, hoping to set up in practice in the South of England. However before he reached England the 1914–18 war had broken out, and as soon as possible he joined the R.A.M.C. His war-time experiences made him more and more sceptical of the reliability of many diagnoses. As a surgeon he was very successful, but he often found that there was nothing to warrant the diagnosis. There was evidently here a problem for which he had had no training.

Accordingly he sought further training that might help, and went to Maghull where under Bernard Hart, T. H. Pear, and others he learned something of the psychoneuroses. An appointment as a lecturer on the psychoneuroses at the London Hospital was offered to him and he settled down as a psychotherapist.

Meanwhile from another angle a similar problem had arisen. Eric Farmer and May Smith had been appointed by the Industrial Health Research Board to investigate Telegraphists' Cramp, supposed to be due to some neuromuscular disability. By comparing a group of telegraphists already diagnosed as having cramp with a similar group telegraphically efficient, it was found that among the former there were many who had no disability except for certain letters. It looked as if the disability was not entirely due to neuromuscular inefficiency, but that some other factor was involved. The suggestion that this was probably psychological was not well received by the board. Professor Greenwood proposed that Dr. Millais Culpin should be asked to interview the subjects already tested, and, in ignorance of the experimental findings, should classify them from the point of view of psychoneurotic symptoms. The report is now ancient history, but it brought Dr. Culpin into the field of industrial psychology and proved to be the first of a number of researches. His appointment as professor at the London School of Hygiene and Tropical Medicine extended his influence, and students training for medical and industrial work in the field of public health had some training in the psychological problems likely to be encountered.

Throughout his life Culpin was a rebel against the accepted order. If some theory or attitude of mind was generally accepted it tended by that alone to be of doubtful value and to need criticism. Often he was right, but sometimes this attitude led to a disregard of something valuable even though it might be linked to apparent error. He often criticised what he called academic psychology, and it was only with difficulty that he was led to see that there had been many developments since his student days. Having been convinced of the value of psycho-analysis, he could not understand why there was so much opposition to it. His highly developed critical faculty tended to make him over-simplify the problems of life, and he thought that if a theory or general principle was clear to him it must be equally clear to others. Once, however, convinced that he had been mistaken, or that two apparent incompatibles had to be accepted in the absence of adequate differentiating data, he could tolerate the two. He once said that an uncle of his, who was a member of one of the more rigid religious sects, was perfectly convinced that his nephew was damned, but on this basis they got on excellently, and the latter bore him no ill-will.

To those in trouble he was the perfect physician, never grudging time or sympathy if he could help. Many a student and "interviewee" has cause to be thankful that he met Dr. Culpin at the right time. Sometimes during interviews for research purposes, he would come across some problem for which the time available was insufficient and he would then arrange for the person concerned to see him privately.

He retired in 1939 but continued to do some clinical work. Temperamentally he was well balanced, never likely to lose his head in an emergency, and he had to an unusual degree the capacity for preventing one experience from impinging on the next. He rarely read novels, for he said he found people much more interesting. He excelled at and enjoyed bridge and was an adept at the more learned crosswords.

He died on Sept. 14, as he had lived, without fuss.

SAMUEL WILLIAM ALLWORTHY

M.A., M.D. Dubl., D.P.H.

Dr. Allworthy died in Belfast on Sept. 13 at the age of 85. He was consulting physician both to the Royal Victoria Hospital, Belfast, and to the Old Charitable Institution.

Entering Trinity College, Dublin, at the early age of 15, he graduated in arts at 19 and in medicine at 20. On qualifying he worked for a time in Darlington before settling in Belfast where he combined general practice with specialist work in dermatology. For many years he was physician to the Benn Hospital for Diseases of the Skin, and it was on his initiative that this hospital was amalgamated with the Royal Victoria Hospital. He had studied for a time at the Finsen Institute in Copenhagen and he became a pioneer radiologist in Belfast. In those early days few precautions were taken, and like others of his generation he suffered later from the frequent exposure to X rays. His hands were disfigured by old X-ray burns and in the last years of his life the skin began to break down: a finger was removed in 1951 and two more fingers had to be amputated in the spring of this year.

During the 1914–18 war he served in the R.A.M.C. with the rank of major. At first he was specialist in dermatology and superintendent of the department of radiology at the Lord Derby Hospital, Warrington, and later he was radiologist at No. 1 Casualty Clearing Station, B.E.F.

Allworthy was a foundation member of the Jenner Institute (later called the Lister Institute of Preventive Medicine), a fellow of the Chemical Society, and a former president of the Belfast Natural History and Philosophical Society. He took a prominent part in the public life of Belfast and was an alderman of the city, thus following a family tradition: his maternal grandfather was the first alderman elected when Belfast became a municipality, and his father was also an alderman. An interest in public health led to his becoming a water commissioner and later he was chairman of the Belfast water commissioners. He was also a justice of the peace.

His family on his father's side had many links with Ireland, and his grandfather, a district inspector of the Royal Irish Constabulary, married a daughter of the Knight of Glin. His wife, the widow of William Boyd Bennet, died in 1933.

GUY JOSEPH BRANSON

B.A., M.D. Lond.

Dr. G. J. Branson, who died at his home in Edgbaston on Sept. 2 at the age of 82, had practised medicine in Birmingham for over half a century. He had been born and bred in that city, and his father was a member of the firm which in 1850 built the Bingley Hall in nine weeks. He was educated at Mason College, Birmingham, in the days before the University of Birmingham had been incorporated, and he took his B.A. Lond. with honours in 1888. Six years later he qualified in medicine and in 1895 he graduated as M.B. After holding house-appointments at Queen's Hospital he settled in practice in Birmingham. During the 1914–18 war his interest in shell-shock cases led him to the study of psycho-analysis, and after the war he continued his work in psychiatry. At the Ministry of Pensions Hospital in Birmingham he became neurologist and chairman of the neurological boards, and physician to outpatients at the psychotherapeutic clinic.

J. F. B. writes: "For nearly 60 years Guy Branson exhibited the highest traditions of medicine to the great benefit of his patients and to the honour and glory of his profession. His brusque manner, his careful scrutiny of men and material, of patient and doctor, may not have brought him the recognition of a popular doctor, but his rigid integrity, his firm honesty of purpose, his searching inquiry into all things reported to be good for his patients entitled him to the term wise physician. He was one of the old school of family doctors and those who were fortunate enough to be his patients found in him always a true guide, philosopher, and friend. He respected academic status and position only when it was coupled with honest endeavour, but all who came into contact with him, be he patient or consultant, experienced a chastening discipline—a discipline which has done more to establish the high standard of British medicine than all the showy exponents of the 'scientific' fashions of the time.

"He had a profound respect for, and knowledge of, psychology which gave him a clear insight into human thought and conduct, and this, coupled with his wide reading and experience, his love of the truth, and sound appreciation of all modern advances, fitted him to assess values. He did not tolerate the shallow enthusiast, but he was kind and encouraging to all who showed an earnest desire to render honest service. He was opposed to the exploitation of medicine, be it private or public. The profession has been ennobled by his services, for he set a high pattern throughout a long and useful life."

Dr. MAX LEDERER, director of laboratories at the Jewish Hospital in Brooklyn, New York, from 1918 until his retirement in 1943, died on Sept. 13 at the age of 67. Dr. Lederer first described, in 1925, the form of acute hæmolytic anæmia which now bears his name.

Notes and News

ALL ROUND THE UNIVERSE

To read the report of the Nuffield Foundation[1] is to experience some of the astonishment of Miranda at what goes on in the world—and outside it. The Foundation exists to advance health and social well-being in Great Britain and the Commonwealth, to prevent sickness, foster research, to favour the care and comfort of the aged poor, and to advance education. In addition, the trustees administer the Oliver Bird Fund for research into the relief and prevention of rheumatism.

Their main interests at present are in fundamental research in biology and sociology; but they are not at all narrow in outlook, for almost the first thing they report is a grant of £200,000 towards the cost of a steerable radiotelescope for the University of Manchester. With this, it seems, we may hope to achieve in radio astronomy during the next twenty years what the Mount Wilson telescope, in America, did for visual astronomy between the two world wars. Already workers in England and Australia, by applying radio and radar techniques to astronomy have found a new and different universe from the one which sufficed for former watchers of the skies. Radio emissions come from space not diffusely but from localised sources which do not correspond with prominent visible stars. These dark "radio stars" interlard the visible stars, and, not unlike their namesakes on the air, await some explanation. A diametrically opposite project supported by the foundation is the sinking of a borehole at Cambridge to determine the geological succession of the rocks. Returning from these astronomical and geodesic excursions to the earth's crust the trustees have granted £25,000 to the University of Cambridge to build a new high-speed electronic calculating machine, which is to be more reliable and slightly faster, and is to have more storage capacity than the already famous EDSAC.

Studies of more direct medical interest include the continuing research on blood-groups at the Nuffield centre in the Royal Anthropological Institute; work at the Lister Institute on bacterial antigens, which may lead to the preparation of materials more suitable for immunisation than crude bacterial vaccines; X-ray and infra-red studies at Leeds University on the molecular structure of collagen; investigations at University College Hospital of the biochemical activities of red cells, and of liver regeneration, and of course, research on the processes of ageing. In the obstetric department of U.C.H. a study, to which the foundation has contributed, is being made, by means of sensitive electronic recording apparatus, of uterine contractions in childbirth. At Oxford the mechanism of drug-resistance in bacteria is being studied, while Cambridge is hard at work on the action of hormones on tissue cultures. Sociological studies are to include the making of a set of social accounts, classifying and presenting all the transactions taking place in the administrative county of Cambridgeshire in the tax year 1953–54. Like those ancient records, the Saxon pipe-rolls, these accounts should tell us a good deal about local, and hence perhaps national, economy. As for personal economy, that forgotten art, Oxford, the home of lost causes, is conducting a statistical survey of the saving habits of a national sample of the populace. On the subject of town and country planning the Foundation displays a frankly inquisitive spirit: "Planning itself needs to be investigated." To this end the trustees have granted £4000 to the department of town-planning at University College, London, for an inquiry into the processes of planning, including the natural history of representative plans, from conception to birth. Moreover, the whole field of social research is to come under the scrutiny of Prof. Barbara Wootton, who is to resign her chair as professor of social studies in the University of London and accept a research fellowship for three years from the foundation. She will assess the results of current sociological research and point out the gaps, beginning with social deviation—"a term which includes not only crime but other forms of social failure, irresponsibility, incompetence, and nonconformity."

Sociology, however, is but one aspect of the study of mankind, and a tame one perhaps compared with those enjoyed by anthropologists in different parts of the Commonwealth. Dr. D. F. Thomson, for instance, of the University

---

[1] Report for the year ending March 31, 1952. Nuffield Foundation, 12, Mecklenburgh Square, London, W.C.1.

Melbourne, went to live with the natives of Arhem Land the Northern Territory of Australia. Even their fellow atives considered these people to be difficult, and at the me they had been attacking pearling vessels in a way that emed to invite reprisals. Dr. Thomson found, when he ot to know them personally, that those who respected their aditions had little to fear. The Foundation has made a rant towards his expenses in visiting this country and ublishing his material. Then, the Pretorian discoveries f fossil remains of new types of ape-men in 1936, 1942, and 948, have thrown new light on the theory of evolution; nd the foundation is contributing to further excavations on he site of the last find.

For biologists, however, man is but one living organism mong many, and not by any means the most fascinating. hus the foundation has had the pleasure of encouraging tudies on such things as the reproductive behaviour in the en-spined stickleback, the hormonal control of ovulation, regnancy, and lactation in marsupials, the evolutionary elationships of the rannuculus in New Zealand, the nervous ystems of sea-anemones, and the family habits of the uatara, the most primitive reptile now living. The report ells of these many projects with enough detail to make the oint of them clear, and with enough reticence to whet the ppetite for more news of them. Any young man hoping o enter research could read this delightful work as a rospectus.

BRISTOL HEALTH CENTRE

On Sept. 16 Mr. Iain Macleod, the Minister of Health, on opening Bristol's new £20,000 health centre at Knowle West housing estate, congratulated the council on making history. Although a few dispensaries and other buildings were taken over as health centres when the National Health Service Act came into being and one cottage hospital had since been adapted, Bristol's health centre, as Mr. Macleod pointed out, is the first to be designed and built for this purpose.[1] It contains 6 suites for general practitioners, each consisting of a consulting-room, examination-room, and waiting-room. These suites have communicating doors so that a pair may be used for maternity and child-welfare clinics out of surgery hours. Eight doctors will use the centre, which has a staff of 12, including 5 nurses and 2 secretaries.

Since the National Health Service began, shortage of building labour and materials have made it impossible to develop health centres widely over the whole country. "Apart from that," Mr. Macleod declared, "it would be foolish to encourage authorities to build large numbers of health centres until it is known what type of health centre is likely to be most useful and popular with patients and at the same time acceptable to doctors. It is better to allow a few health centres of different types to be tried first in areas where there is a real need for better accommodation for doctors' surgeries and clinics." By studying these first experimental health centres the Minister hoped to discover the sort of centre which would enable doctors to give their best work and which would also be liked by their patients. "It is no use," he said, "putting up a palatial building with every modern facility if, in order to justify itself economically, it has to serve so large an area that the patients are obliged to travel inconveniently far. On the other hand, we expect that patients will be content to travel a little further than usual if the consulting and waiting rooms are pleasant and comfortable and, most important of all, the doctors a little less pressed for time." But he did not intend to prejudge the future of health centres. He would watch this and other experimental centres closely, and he would be "interested to know to what extent general practitioners, accustomed to practice from their private surgeries, find benefit from working with their colleagues under one common roof—whether this will lead to a desire for more co-operation or to a confirmation of a preference for working as individuals."

INSTRUCTION IN BREAST-FEEDING

The Central Council for Health Education is issuing a set of thirteen wall charts as an aid to teaching medical and nursing students the technique of breast-feeding. These charts have been produced with the coöperation of Dr. R. C. Mac Keith and the department of medical illustration, Guy's Hospital Medical School. The authors suggest only that breast-feeding is more enjoyable and simple, and is associated with rather better health in the baby, than artificial feeding; they make no dogmatic assertion that breast-feeding is essential. Some of the reasons for success and failure in breast-feeding are illustrated; and details are given of a technique based mainly on Dr. H. K. Waller's successful work. A small pamphlet is available for distribution to individual students. The set of charts may be hired, at a cost of one guinea a week, from the council, Tavistock House, Tavistock Square, London, W.C.1.

University of London

On Nov. 10, 11, 12, 13, and 14, at 5.15 P.M., at the London School of Hygiene, Keppel Street, W.C.1, Prof. Henry E. Sigerist (Yale University) will deliver a course of Heath Clark lectures on Landmarks in the History of Hygiene.

Royal College of Surgeons of England

A course on anæsthetics will be held at the college from Sept. 29 to Oct. 10. There will be two lectures in the morning and two in the afternoon. A course of lectures on pharmacology will also be given from Oct. 13 to 17 at 5 P.M. and 6.15 P.M. daily. A course of surgery lectures and clinical conferences will also be held at these times from Sept. 29 to Oct. 16. Further particulars may be had from the secretary of the faculty of anæsthetists at the college, Lincolns Inn Fields, London, W.C.2.

Ophthalmological Society of the United Kingdom

The annual congress of this society will be held next year from April 23 to 25 at 1, Wimpole Street, London, W.1, under the presidency of Mr. Alex. MacRae. Prof. Arnold Sorsby, Prof. Robert Cruickshank, and Mr. Derek Ainslie will open a discussion on the Scope of Antibiotics and Chemotherapeutic Agents in Ophthalmology, and Sir Geoffrey Jefferson, F.R.S., will deliver the Bowman lecture. Further particulars may be had from the hon. secretaries of the society, 45, Lincoln's Inn Fields, W.C.2.

British Postgraduate Medical Federation

A further series of lectures on the *Scientific Basis of Medicine* has been arranged for the coming session. The lectures are specially designed for research-workers and specialists in training. The first lecture will be given by Prof. J. Z. Young, F.R.S., in the Beveridge Hall of the Senate House, London, W.C.1, on Oct. 7 at 5.30 P.M. His subject will be the Influence of Language on Medicine. Subsequent lectures will be given on Tuesdays and Thursdays at 5.30 P.M. at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1. *Admission is free without ticket.*

King's College Hospital Medical School

Willshire Memorial Research Scholarship.—Applications are invited for this prize which was founded in 1948 to encourage research in cardiology. It may be held for the purpose of study and travel abroad. Further particulars may be had from the dean of the school, Denmark Hill, London, S.E.5.

B.M.A. Scholarships and Prizes

The council of the British Medical Association is offering an Ernest Hart scholarship (£250), a Walter Dixon scholarship (£250), one or more research scholarships (£200 each) to candidates qualified to undertake research in any subject (including State medicine), and an Insolde scholarship (£250) for research into venereal diseases. Application must be made not later than March 31, 1953, and further particulars may be had from the secretary of the association, B.M.A. House, Tavistock Square, London, W.C.1.

The council is also offering during 1953 an Occupational Health prize (£50) for essays or studies in this field; a Katherine Bishop Harman prize (£75) for research on the disorders incident to maternity; a Sir Charles Hastings prize (50 guineas) and a Charles Oliver Hawthorne prize for an essay on a clinical subject by a general practitioner. Further particulars may be had from the secretary of the association.

Hunterian Society

At the annual party to be given by this society to fellows and their friends on Oct. 2 at 41, Portland Place, London, W.1 (by kind permission of the Ciba Foundation), the books, manuscripts, &c., acquired by the society during the year will be on view in the library. The exhibition is open for the week following (Oct. 3-10), from 4.30 to 6 P.M., to all who are interested.

---

[1] Wofinden, R. C., Parry, R. H. *Lancet*, 1952, i, 1297.

Memorial to Dr. J. C. Muir

A memorial tablet has been erected to Dr. Muir at Whipps Cross Hospital, Leytonstone, London, E.11, where he was superintendent for over 20 years. It will be unveiled at 3 P.M. on Saturday, Oct. 18, and his friends are invited to attend the ceremony.

W.H.O. Committee for South East Asia

At the fifth session of the South East Asia regional committee of the World Health Organisation, which ended in Bandung on Sept. 9, Dr. M. Soerono, the chairman, laid stress on the desire of delegates to place the emphasis of W.H.O. help on supplies of equipment, rather than on procurement of foreign personnel. The committee adopted a strong resolution urging further modification of W.H.O. policy in this respect. Health projects for 1954, involving W.H.O. assistance and totalling over 2 million dollars, were endorsed. These projects will require a further $1^1/_2$ million dollars from UNICEF and other sources, making a total international expenditure of 4 million dollars.

Contraceptive Technique

A lecture and demonstration on contraceptive technique will be given by Mrs. Marie Stopes, D.SC., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on Thursday, Oct. 2, at 2.30 P.M. Tickets must be obtained in advance from the clinic.

Biology of Deserts

The Institute of Biology is holding a symposium on the Biology and Productivity of Hot and Cold Deserts at the Royal Institution, 21, Albemarle Street, London, W.1, on Sept. 25, 26, and 27. The 30 speakers will include scientists from Australia, France, the Gold Coast, North Africa, Israel, and the United States. Papers are to be given on the physical environment in deserts, the means by which plants and animals are able to exist in desert regions, the effects of hot and cold on man, how man can adapt himself to extreme conditions, and the economic aspects of obtaining increased food-supplies from arid regions. Further particulars may be had from the institute, Tavistock House South, Tavistock Square, London, W.C.1.

Eighteen doctors and others concerned in the health of industrial workers from 13 Western European [illegible] arranged by the British Council, o[illegible] Britain, which opened in Manche[illegible] continued in West Cumberland an[illegible] the course is being directed by P[illegible] [illegible]hn Craw, m[illegible] [illegible]irmingham the Birmingham branch of the [illegible] Medical Officers, of which Dr. F. H. Tyrer is hon. secretary, has coöperated in arranging the programme.

Diary of the Week

SEPT. 28 TO OCT. 4

Wednesday, 1st

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of History of Medicine.* Dr. George Edwards: A Note on John Snow and the Institut de France. Dr. W. H. McMenemey: The Water Doctors of Malvern.
5 P.M. *Section of Surgery.* Prof. F. A. R. Stammers: The Surgeon's Environment.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. H. Haber: Histology of Normal Skin.

MANCHESTER MEDICAL SOCIETY
4.30 P.M. (University of Manchester.) Prof. J. Crighton Bramwell: Heart-disease and Pregnancy.

[illegible] OF ANÆSTHETISTS
[illegible]ral Infirmary.) Dr. H. O. J. Collier: New in Muscle-relaxant Drugs.

Thursday, 2nd

ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of United Services.* Surgeon Lieut.-Commander W. H. B. Ellis: The Human Factor in Naval Aviation; wit[illegible] to Deck Landings.
8.15 P.M. [illegible] Dr. Macdonald Critchley: Tactile Th[illegible]ference to the Blind.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. R. W. Riddell: Mycology—Diagnosis of Mycotic Infections.

Friday, 3rd

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. E. M. Wigley: Eczema. (Clinical demonstration.)

Births, Marriages, and Deaths

BIRTHS

AUMONIER.—On Sept. 13, at Guy's Hospital, to Nell (née Col wife of Dr. F. J. Aumonier—a daughter.

BARRY.—On Sept. 20, at Royal Simpson Memorial Pavilio Edinburgh, to Monica (née Craig), wife of Dr. Claude Barry— [illegible]

[illegible] at the Bristol Maternity Hospital, to Joy [illegible] wife of Dr. F. G. Bolton—a daughte

CLARK.—On Sept. 7, at Bromley, Kent, to Mary Rose (née Harr wife of Dr. David Clark—a son (Alan Trelawney).

DELLER.—On Sept. 20 to Patricia (née Palmer), wife of Dr. Pete Deller, 49, Chester Square, S.W.1—a daughter.

RUTTER.—On Sept. 13, to Mary (née Milton), wife of Dr. Frank Rutter, of [illegible] a daughter.

SMITH.—On Sep[illegible] Hospital, London, to Lily Janet, [illegible] daughter.

MARRIAGES

BROWN—RICHARDSON.—On Aug. 27, Robert W. W. Brown, M.B., to F. C. Ruth Richardson, F.R.C.S.

HUTCHISON—PRICE.—On Sept. 13, in Toronto, James Graham Pinney Hutchison, M.B., to Margaret Jane Price.

DEATHS

CULPIN.—On Sept. 14, Millais Culpin, M.D. Lond., F.R.C.S., 78, of 17A, Hatfield Road, St. Albans, late of Queens Shanghai, Loughton, and Park Village East.

GOW.—On Sept. 19, at Robinwood Cottage, Kingston Vale, S.W Alexander Edward Gow, M.D. Lond., F.R.C.P.

GRAHAM-SCOTT.—On Sept. 18, at Eastbourne, Thomas Gra Scott, M.R.C.S.

HODGSON.—On Sept. 18, 1952, Stanley Hodgson, M.D. Lo LL.B., J.P.

ROW.—On Sept. 13, at Stanton Lodge, Fleet, Hants, Ch Martin Row, M.B.E., Croix de Guerre, M.R.C.S., lieut.-col R.A.M.C. retd.

TREDGOLD.—On Sept. 17, at St. Martin's, Guildford, Alfred Tredgold, M.D. Durh., F.R.C.P., F.R.S.E., consulting ph to University College Hospital, London, aged 81.

Appointments

JONES, G. A. H., M.B. Birm.: appointed factory doctor, W district, Cumberland.

MACMILLAN, S. C., M.B. Glasg., D.P.M.: consultant psych (deputy medical superintendent), Cefn Coed Hospital, Swansea.

O'CALLAGHAN, ANNE, M.B. N.U.I., D.C.H.: asst. school M.O., Brig

PERRY, KENNETH, M.A., M.D. Camb., F.R.C.P.: cons physician, Royal Masonic Hospital, London.

REID, J. J. A., M.B. St. And., D.P.H.: asst. county M.O., Buc hamshire.

WALLIS, A. L., M.B. Edin.: appointed factory doctor, Da district, Cumberland.

WARD, A. B., M.B. Durh., D.A.: asst. anæsthetist (consu to the West Cumberland group of hospitals.

Sheffield Regional Hospital Board:

[illegible] M.B. Leeds, F.R.C.S.: consultant sur [illegible] Infirmary, and Derby City Hospital.

[illegible].M. Oxfd, M.R.C.P.: consultant phys [illegible]istrict Hospital, and Victoria Hos [illegible]

WILD, G. D., M.R.C.S.: asst. chest physician with duti chest clinics in the South Derbyshire area.

Colonial Service:

BARNES, G. T., M.B. Birm.: senior pathologist, Nigeria.
BATEMAN, F. J. A., M.B.: resident M.O., Northern Rhodesi
BUCK, S. C., M.A., M.B. Camb.: senior pathologist, Nor Rhodesia.
COTTON, S. P. F., M.B.: M.O., Fiji.
DE BEAUX, J. L. M., M.B. Madras: M.O., Fiji.
DELANEY, JOYCE, M.B. N.U.I.: M.O., Federation of Malaya.
DURHAM, N. A., M.D. Bombay, M.R.C.P.: M.O., Federation of Malaya.
GARDINER, A. S., B.M. Ox[illegible] Malaya.
GATT, E. J., M.D. Malta: [illegible] a.
GRAVES, JOHN, M.R.C.S.: [illegible] of Malaya.
LESLIE-SPINKS, A. J., B.M [illegible] Trinidad and
SIUNG, O. H., M.B. Edin[illegible] Tobago.
SUTHERLAND, J. A., M.B. Glasg.: M.O., Federation of Malaya.
SWAN, T. T., M.CH. N.U.I.: M.O. (special grade) Aden.
TANNER, J. W., M.B. Birm.: M.O. Uganda.
THORNTON, T., M.B. St. And., F.R.C.S.: surgeon specialist, Federation of Malaya.
TUDOR, C. E., M.R.C.S., D.A.: anæsthetist, Trinidad.
WOLF, J., M.B. N.U.I.: M.O., Federation of Malaya.
YHAP, SHEILA A., L.R.C.P.E.: M.O., British Guiana.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

CORRIGENDUM: *New Atropine Substitute.*—In our annotation last week the reference to J. A. Marks's paper should have been *N.Y. St. J. Med.* 1952, **52**, 1783.

PERMANENT FACIAL PARALYSIS

THE RÔLE OF SURGICAL SUPPORT *

C. R. McLaughlin
M.B. Camb., M.B. Edin., F.R.C.S.E.
ASTIC SURGEON, QUEEN VICTORIA HOSPITAL, EAST GRINSTEAD

[HE problem of permanent facial paralysis is both ious and complex. Its various aspects have been plored by a host of experts with specialised interests neurologists, otologists, and general surgeons—and erefore the precise scope of this paper should at once defined. It is concerned with the rôle of static and namic support by surgical methods for those patients th permanent and irrecoverable lesions of the facial rve, who, for whatever reasons, are unsuited to urosurgery.

It includes a review of 55 cases which I have treated plastic surgery.

SELECTION OF CASES

It is very important that patients should be properly lected before they are submitted to such operations.

Unquestionably, reconstitution of the facial nerve, ether by suture, graft, or decompression, is the best eatment where it is possible (Cawthorne 1952). There e, however, many cases in which nerve repair is likely be hopeless; for instance, after radical removal of a alignant parotid gland, in certain middle-fossa fracres, in persistent congenital lesions, in birth injuries, in long-standing palsies—and these are the cases st suited to plastic surgery. In quite a different type case, where there is very slow recovery, it may be *ise to give temporary* support. The patient's age is ot very significant, and it may even be justifiable do this type of operation in children. Electromyoraphy is sometimes of value in assessing cases before peration; but it is an ancillary method, of only econdary value. Clinical judgment is, as usual, the ost important factor.

With each patient the defect has to be analysed arefully. In a fully developed case there will be sagging f the mouth and of the cheek, ectropion of the lower d, and lowering of the eyebrow on the affected side. he patient himself may complain of dribbling, of ifficulty in chewing, or of asymmetry of his mouth ith an appearance of depression and stupidity; also f epiphora and lagophthalmos. Corneal ulceration s rare.

MATERIALS

A great variety of materials has been used by different urgeons to support the face.

Silk has often been tried, but is unsatisfactory because t tends to cut out. There is, however, no serious objection o its use with proper precautions as a fixation suture in relation to fascia.

Wire slings have had a great vogue in the past, particularly in the form of stainless steel and tantalum; they have been strongly recommended by Sheehan (1946) and other surgeons. However, wire is now regarded by many as dangerous and unreliable. Even tantalum is prone to electrolytic action, and this reaction has been reported as occurring between buried tantalum and lead. It could also occur in relation to dental fillings.

Wire gauze, usually fine stainless-steel or tantalum gauze, has been used. It has proved satisfactory in the repair of certain large hernias; but it is unsatisfactory in the face, because it is still liable to undergo fragmentation, and a wide dissection is required to insert it.

Fascia lata is, in my view, the ideal material. It is strong and not prone to stretch. It should be taken, preferably by open operation, from the toughest portion of the fascia lata—namely the iliotibial tract. This is in fact the tendon of the tensor fasciæ latæ, and is covered with paratenon. For clinical purposes it may be regarded as a flattened tendon and it retains all the characteristic advantages of a tendon even under tension. When transplanted it behaves as a living graft nourished by small ingrowing blood-vessels.

Lastly one may use *muscle*. Strips of muscle, partly torn from their parent muscle belly, are not ideal. They are likely to become separated from their nerve-supply and blood-supply, and they will then undergo fibrosis and cease to act as muscles. But the use of a complete muscle with its tendon intact, in conjunction with fascia lata, is a different matter. This undoubtedly is a very satisfactory combination with a wide sphere of usefulness.

STATIC VERSUS DYNAMIC SUPPORT

It is proper at this stage to set down the indications for dynamic as opposed to static support.

In a normal person the face is highly mobile, and ideally there is no doubt that for paralysed patients dynamic support is best; but it must be of such a kind that it also offers static support while the face is in repose (fig. 1). With technique as it is at present, dynamic support to the forehead or the eyelids is often unsatisfactory, and in my opinion static support is best in these areas. Dynamic support is certainly applicable to the mouth and cheek if the patient is suitable—i.e., if he is not stupid or too old. But it always requires patience and effort for anyone to overcome the difficulties of dissociating and reassociating two such primitive functions as chewing and smiling. Also there are likely to be some involuntary mouth movements which cannot be entirely suppressed when the patient is eating. Finally it must be remembered that, technically, static support is much the simpler operation.

TECHNIQUE OF STATIC SUPPORT

In static support one must have two fixed points. The lower point lies at the corner of the mouth, though it is also linked medially with the functioning half of the oral sphincter on the unaffected side. The upper point of fixation can be either the temporal fascia, 4 or 5 inches away, or round the zygoma; but it has been argued that the best point lies nearer the mouth (McLaughlin 1949). The nearest bony structure in the right direction is the malar, only $1^3/_4$ inches away. A hole can easily be drilled near the lower edge of the anterior part of this

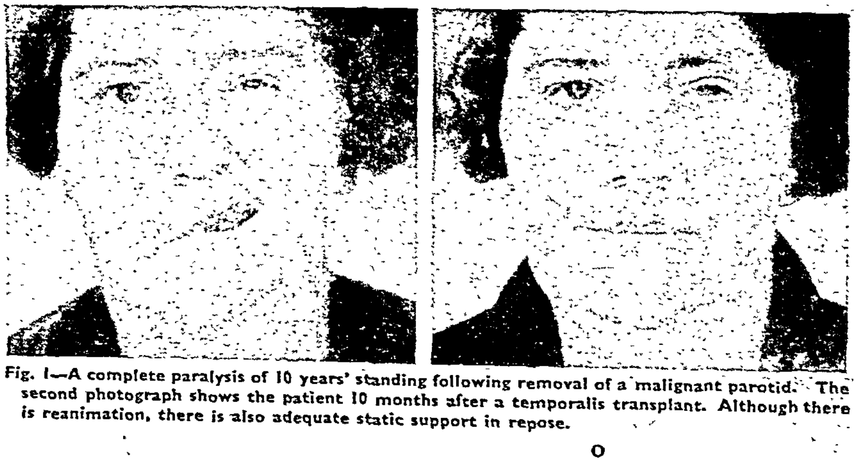

Fig. 1—A complete paralysis of 10 years' standing following removal of a malignant parotid. The second photograph shows the patient 10 months after a temporalis transplant. Although there is reanimation, there is also adequate static support in repose.

6736

bone. This is close to the origin of zygomaticus major, and the sling will finally follow the course of this important muscle.

The operation is carried out as follows :-

Three tiny incisions are made, one on the upper lip, one on the lower, and one on the lateral side of the mouth on the paralysed side. Two $^1/_4$-inch strips of fascia lata have already been cut, one 7 inches and the other 5 inches long. The longer of these is then inserted with the Blair needle in a figure-of-eight so that it reaches the unparalysed portion of the sphincter just beyond the midline in both upper and lower lips. The two ends are brought out of the lateral incision and sutured together with silk. The second strip is looped round the double loop at the corner of the mouth.

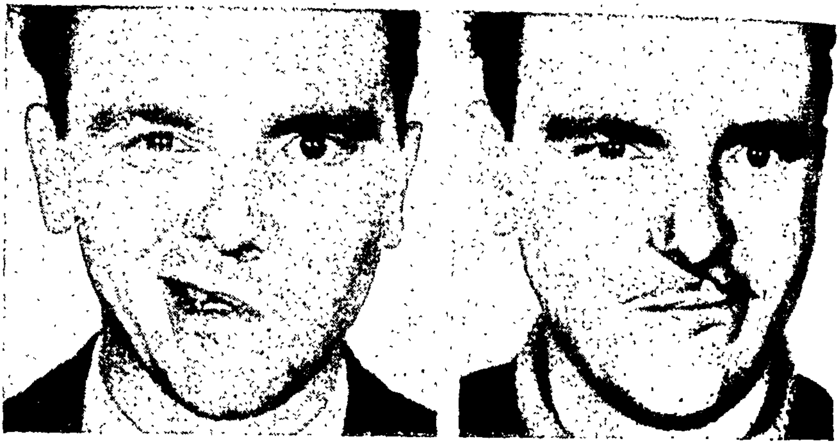

Fig. 3—Left facial paralysis. Range of cheek movement before and after total temporalis transplant. With practice the patient can also produce a natural-looking smile. *In this case the coronoid was approached by sectioning the zygomatic arch and turning down the bone together with the masseter origin.*

The malar bone is exposed through a separate incision. After stripping a small area of periosteum, a hole is made with a dental drill and enlarged sufficiently to admit a small sucker-nozzle. Using a wire noose, one end of the fascia lata is drawn through this hole; the other end is then brought up, but not through the hole, and the two ends are twisted together and finally sutured together. The device of twisting is useful, because in this way the correct tension may be gauged.

In all these manœuvres it is important, by the use of small towels, to prevent the fascia coming in contact with the face. With silk sutures it is particularly necessary to preserve asepsis. The four small incisions should lie so that they are virtually self-closing, and when sutured they will then not leave conspicuous scars. It is always wise to apply pressure to the cheek with a crêpe bandage to prevent postoperative œdema.

In this technique certain points require emphasis. First a considerable degree of so-called overcorrection has to be produced, because the muscles on the unparalysed side are without tone under the anæsthetic. As soon as the patient is conscious, most of this overcorrection will disappear. Secondly, it is important to adjust the tension of the figure-of-eight so that the mouth is not made too small. If the tension is rightly assessed it will correct the ectropion of the lower lip but will avoid a rigid mouth. Relaxation of the normal half of the sphincter then allows a wide enough opening of the mouth.

A well-judged static operation will tend to straighten the nose, and centre the philtrum; it will control any bulging of the buccinator muscle, and it should also restore the normal curve of the cheek (fig. 2). One may note in passing that the so-called face-lift operation tends in these patients to do the opposite and to achieve only a flat cheek.

REANIMATION BY DYNAMIC SUPPORT

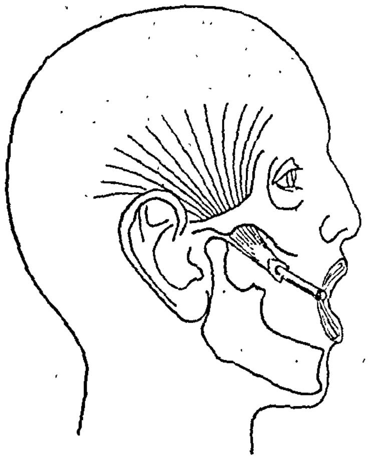

Fig. 4—Diagram of temporalis sling showing relationship of transplanted temporalis and fascial slings.

This brings us to the question of dynamic support. Muscle transplantation cannot hope to give the *quality* of reanimation that nerve surgery can achieve; but where nerve surgery is not feasible muscle transplantation offers the best alternative. It is the method of choice where there is an irrecoverable nerve lesion, where the patient is over twelve but under fifty years of age, and where he is coöperative and intelligent enough to make the best use of an unusual and anomalous means of expression (fig. 3).

There are a number of alternative ways of using a muscle transplant to achieve facial movement. First the masseter may be used in strips. It is however a bad principle to split a muscle belly, and there is inevitably some risk to the nerve-supply of this muscle. Secondly, fascia lata brought up from the corner of the mouth may be sutured to the masseter; but this may not give secure fixation. Similarly, fascia lata attached to the temporalis muscle may be used: this has the definite disadvantage of conferring only a small range of movement, but it is appropriate to certain rare cases of bilateral paralysis, where a fixed malar sling is too

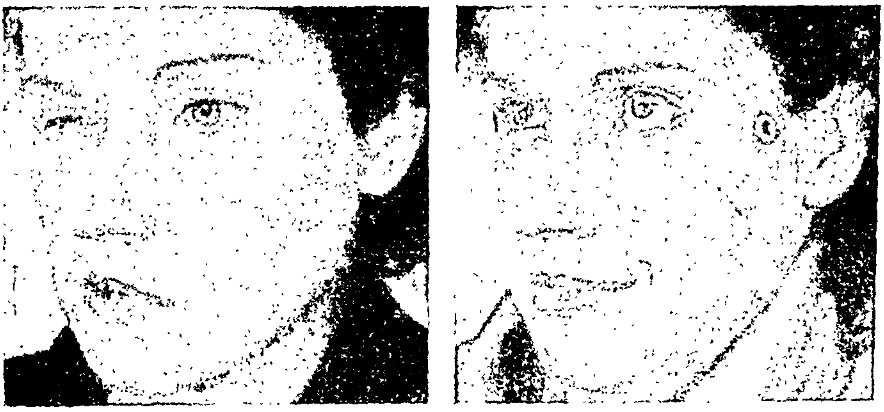

Fig. 2—Partial paralysis of 25 years' duration, following otitis media. *Gross asymmetry of face with skeletal distortion.* Treated by fascia lata sling to malar, with Bunnell type of removable wire for later adjustment; seen 10 days after operation.

igid. Or, a portion of the temporalis muscle may e turned down as a muscle flap after the method of illies (1934). This is a very difficult operation, and s apt to give rather a cumbersome result.

The last, and probably the best, method is to use the emporalis in its entirety, firmly secured to a strip of ascia lata (fig. 4). As this appears to me to be the nethod of choice and has never been published, it may be wise to describe it fully.

It involves a direct open approach to the coronoid process of the mandible, so that the insertion of the temporalis muscle may be preserved intact. There are several possible routes to the coronoid:

1. It may be approached through the masseter muscle. But this is an unsatisfactory route and involves serious trauma.
2. It may be approached by dividing the zygoma on each side of the masseter origin, and turning down a large single flap of bone and muscle. This gives a very good view, but involves a major dissection which seems hardly justified.
3. One may go through the skin in front of the masseter in the narrow space between the zygoma above and Stensen's duct below. This is a good method, but it is usually impossible to reach the coronoid by this route unless the temporomandibular joint is dislocated forward *on* that side.
4. The coronoid may be approached from within the mouth.

This last may appear a difficult approach, but it involves very little trauma. There is no skin incision. The condyle of the mandible is held in dislocation, and the jaw is jacked widely open with a cleft-palate gag. It might be thought that this would involve a serious risk of sepsis, but with the routine use of antibiotics the risk appears to be very small, particularly if no sutures are buried near the intra-oral incision. The function of the temporomandibular joint is not disturbed by this procedure, nor is the power of mastication curtailed.

Whatever the anatomical approach to the coronoid, the technique of dynamic support should be a standard one:

> After the necessary dissection to expose the upper part of the coronoid, a hole is drilled in the bone near the apex. A wire loop is then passed through this hole, and the coronoid is divided a little below the hole. The loop of wire is used to draw the fascia lata through the hole, and both ends of the fascia are then brought through a single subcutaneous tunnel down to the figure-of-eight at the corner of the mouth. This must be done in such a way that the fascia and the small portion of coronoid are free to follow a direct line and to run easily in the soft tissues.

In the early postoperative phase it is important to encourage gentle active movements within the limits of comfort, for adhesions are the most likely difficulty with this type of operation.

CONSERVATIVE METHODS

It may be well to refer to some conservative methods of support, that either avoid surgery or require a less complex technique. First, a hook to lift the corner of the mouth may be fixed to the denture, or externally to the ear. This, except after a nerve repair, is a bad device unless for very temporary use, since it stretches the oral sphincter and deforms the mouth. Secondly, an intra-oral flange may be built into the denture to give support in the upper buccal fornix. This is a good method for elderly patients; but if the patient is edentulous, as is usual, it may be difficult to hold the heavy denture in position. Thirdly, the method of supporting the face by skin advancement alone, the so-called face-lift operation, has a limited use, but it is insufficient in the very old, where it might otherwise be most helpful. However, while it is not as effective as fascial slings, it may enhance the result produced by fascia, and it has its uses on occasion.

The best device for supporting the face temporarily in cases of Bell's palsy (or any other paralysis which is likely to recover spontaneously) is plain zinc oxide strapping. This is certainly unsightly, but it *does* give the proper kind of temporary support if applied carefully, and in any case about 80% of Bell's palsies make a full and rapid recovery, usually without any treatment (Muller 1952).

EYELID SURGERY

We now come to the problem of eyelid surgery, including the relief of frontalis paralysis. Both symmetry of the face and also vision may be marred by a sagging eyebrow, when the frontalis muscle is paralysed. Transposition of the frontalis is an operation which has been advocated and is easy to do, but the effect of reanimation usually wears off as the muscle becomes scarred. As so often, the simplest operation is probably the best. This consists in excising an ellipse of skin and of paralysed muscle immediately above the affected eyebrow. It may be necessary to remove as much as half an inch in height at the centre of the ellipse.

As regards eyelid surgery we should in a severe case have four objectives—to relieve the patient's epiphora, to narrow the palpebral fissure, to lessen the lagophthalmos, and to prevent corneal ulceration or conjunctivitis due to exposure.

With regard to epiphora it is necessary to understand the physiological process of lacrimal drainage. Normally

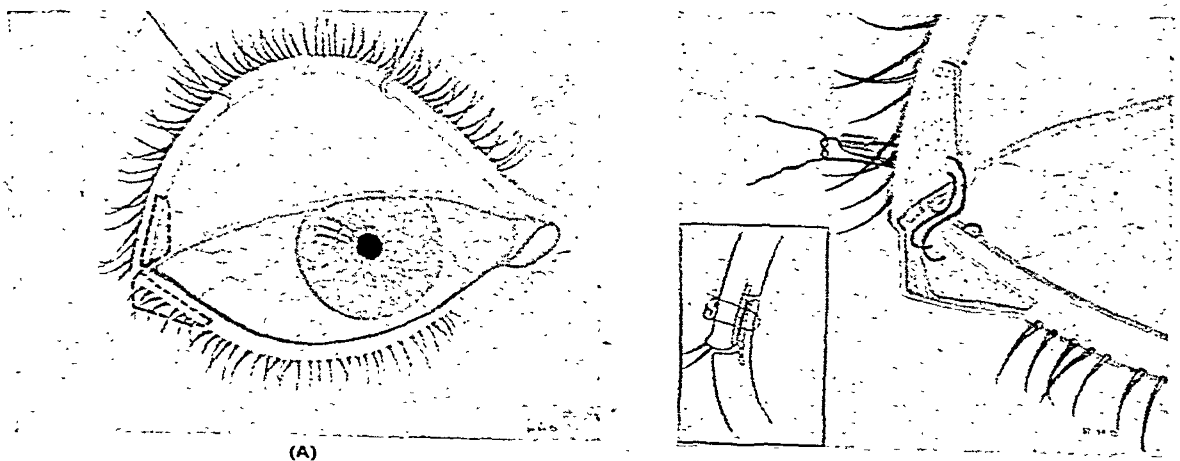

Fig. 5—Diagrams showing (A) the incision and (B) the method of suturing recommended for a lateral tarsorrhaphy, with overlapping of the tarsal plates. The operation is designed both to elevate the lower lid and to draw it in a lateral direction.

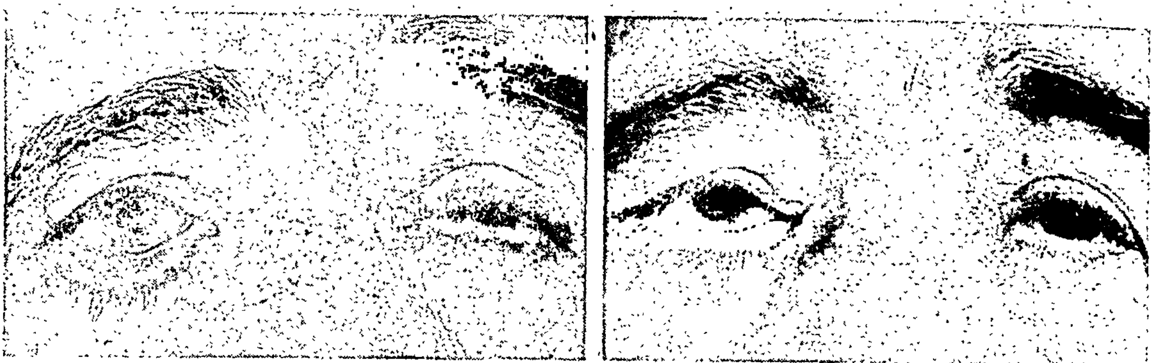

Fig. 6—Elderly patient (73) with severe epiphora. Relieved by lateral overlapping tarsorrhaphy, transposed flap at inner canthus, and "three-snip" to canaliculus.

tears tend to collect and form a tear lake at the inner canthus. The further passage of the tears into the lacrimal sac is assisted by the action of the orbicularis oculi. The lacrimal portion of this muscle is attached to the fascia covering the lacrimal sac. When the muscle contracts it pulls on the fascia and dilates the sac. It also shortens and widens the lower canaliculus and inverts the punctum. This occurs each time the patient blinks. It is probable that the tears pass from the lacrimal sac into the nose by gravity aided by capillary attraction. Thus in paralytic epiphora the following factors are likely to cause difficulty: there is no contraction of the orbicularis to dilate the sac; the punctum is not in contact with the eye and is usually stenosed; the caruncle is unduly exposed and becomes enlarged; and the tear lake lies in the middle of the sagging lid away from the punctum. Finally, undue exposure of the eye leads to excessive lacrimal secretion.

Ectropion of the lower lid is best relieved by an overlapping lateral tarsorrhaphy (McLaughlin 1951) (fig. 5). This will carry the tarsal plate both up and out, and will restore not only its proper position but its normal tension. At the same operation as the tarsorrhaphy, it is also necessary to enlarge the lacrimal opening. This is done by what is known as the three-snip operation. First the roof of the canaliculus is slit for a short distance after dilating the punctum; secondly, a vertical cut is made on the inner aspect of the punctum; and thirdly a triangle consisting of the posterior wall of the canaliculus is excised. This makes a new ostium much nearer the sac. If trouble arises from an enlarged caruncle, this is best treated by partial excision. In the worst cases internal canthoplasty, using a transposition flap, is useful. If these methods are properly carried out, the tears will drain into the nose quickly enough for the eye to remain dry under normal conditions (fig. 6). The eye will be sufficiently covered when the lids are open, and the cornea will be safe when the patient is asleep.

ANALYSIS OF OPERATIONS

This series of 55 patients does not include the small number for whom no surgical treatment of any kind was indicated. The great majority of the lesions, including some that were incomplete, were permanent and therefore required operation. Most of the palsies were due to gross damage to the facial nerve, the commonest causes being mastoid surgery, parotidectomy, and birth trauma.

Owing to the unwarrantably pessimistic attitude of many doctors, only a few patients were seen within a year of onset of the paralysis, and many had waited twenty years or more. For the whole series, the average duration of paralysis before surgical treatment was fifteen years, and in 2 cases it exceeded fifty years. The age of patients ranged from thirteen to eighty.

As has been emphasised, the temporalis transplant is not suited to every patient, and a careful and critical selection is necessary. On this basis a malar sling has been used on 34 occasions, and a temporalis transplant on 11, in each case using the methods described. The need for surgery to relieve the associated epiphora can be judged from the fact that 44 patients have required surgery to the lower canaliculus and 38 have had a tarsorrhaphy by the overlapping technique.

Sepsis in relation to fascial grafts is alleged to be a serious and not infrequent complication. In this series it has occurred on 3 occasions (just over 6%) and in each instance it was related to silk fixation sutures. When these were later removed, healing followed without delay, and the efficiency of the sling was unaffected.

The following summary shows the operative methods used:

Number of patients	55
Range of age at operation	13–80 years
Average duration of paralysis	15 years
Number of operations:	
Malar sling	34
Temporalis transplant	11
Lateral tarsorrhaphy	38
Three-snip to canaliculus	44
Face-lift	4

The results can be roughly assessed by the photographs, though these unfortunately give little or no idea of the degree of reanimation achieved. The object of illustrating results ought to be not so much to advertise the success of new procedures as to demonstrate their scope and limitations. However, from the patient's point of view, symmetry of the face in repose is a major achievement, and a little reanimation greatly enhances the result.

CONCLUSIONS

I would like to summarise certain points which seem to me of special importance.

It is essential to avoid a fixed routine; each patient must be assessed as an individual problem. Even in cases of established facial paralysis there is a wide variety of clinical circumstances. Therefore, the most effective operation suitable to the patient must be selected. For most younger patients a temporalis transplant is best; but static support to the malar bone is easier to carry out, though less effective.

Permanent overcorrection by fascial slings is almost impossible, owing to limitation by the buccinator and mucosal attachments to the mandible. There should be no serious risk of progressive loss of support after the operation, through stretching and so on. Fascia lata does not stretch, and the fixation at both ends should be secure if the operation is properly carried out. There is always the appearance of deterioration due to return of tone on the normal side, but when the patient is re-anæsthetised overcorrection reappears. A dental flange is a useful but inferior alternative.

Most of these patients suffer from epiphora in some degree, and it should never go untreated. 95% of those with this symptom have been greatly improved by very simple methods.

It is wise to remember the gravity of the whole roblem. Bunnell (1927), describing the untreated atient, says: "In facial paralysis, joy, happiness, orrow, shock, surprise, all the emotions have for their ommon expression the same blank stare." But Tagliacozzi, writing in 1597, strikes a more cheerful and onstructive note. He says:

> "We bring back, refashion and restore to wholeness the eatures which nature gave but chance destroyed . . . not as a mean artifice but as an alleviation of illness . . . For although the original beauty of the face is indeed restored, yet this is only accidental, and the end for which the physician s working is that the features should fulfil their offices according to nature's decree."

SUMMARY

The indications for surgical support by reconstructive methods in patients with permanent facial paralysis are discussed.

The relative advantages of reanimation by dynamic rather than static support are described. A new method is suggested, using transplantation of the entire temporalis muscle.

The indications for treating epiphora by simple methods are set out.

Experiences with a personal series of 55 patients are summarised.

I am very grateful to my colleagues at East Grinstead, whose kindness in referring many of these patients has made it possible to collect this material in the past five years. It is also a pleasure to acknowledge my debt to Mr. T. G. Ward for valuable help in working out an approach to the coronoid, to Mr. R. H. Dale for the drawings, and to Mr. G. Clemetson for the photographs.

> "The pressing problems of our time are not, with the knowledge available to us, amenable to the usual methods of preventive medicine. They are diseases obscure in origin and chronic in their course, such as the several forms of heart and arterial disease, diabetes, cancer, rheumatoid and other forms of arthritis."—Boas 1947.

Some of these diseases have a clearly defined social incidence and affect to a greater degree particular classes of our society; others are more prevalent in workers in certain occupations. Some cancers more commonly affect the lower strata of society, and, until recently, hypertension and coronary thrombosis were seen more often in the professional classes. Ryle (1948) aptly remarked that with ætiology—the first essential for prevention—and with prevention itself, the majority of physicians and surgeons have curiously little concern. The problem of the ætiology of carcinoma of the lung remains unsolved and the results of present methods of treatment are poor. Although surgery has placed it among the curable diseases, Brock (1948) reported that only 11% of 666 cases seen over the seven years 1941–47 were operable. A reasonable figure for the present operability-rate is 15%.

INCIDENCE

Whereas twenty-five years ago it was a rare disease, carcinoma of the lung now occurs nearly as often as carcinoma of the stomach and more often than cancer of the colon: indeed at certain hospitals in America it has become now the commonest visceral cancer in men. The third annual report of the Liverpool Cancer Control Organisation (1947–48) states that "there would appear to be little doubt that there is an actual increase in the incidence of this disease, which, in man, is now assuming numerical importance comparable to that of malignant disease of the breast in the female." In 1944 cancer of the lung and mediastinum constituted 8% of the 2668 cases of cancer registered with this organisation; this proportion rose in 1947 to 10·4% of 3875, and in 1949 to 12·2% of 4384. In 1947 and 1949 only carcinoma of the breast and rodent ulcer were registered more frequently than cancer of the lung and mediastinum; the percentages of carcinoma of the breast (which had the highest incidence) were 15·9 in 1944, 14·9 in 1947, and 12·5 in 1949. The corresponding figures for carcinoma of the stomach were 7·4, 9·6, and 7·5. Kennaway and Kennaway (1947) in a careful statistical study of death-certificates in England and Wales from 1928 to 1945 present evidence that the increase is at least partly real. In our opinion the increase is real and cannot be accounted for solely by improved diagnostic methods and a greater awareness of the disease amongst doctors.

POSSIBLE CAUSES OF THE INCREASE

In considering this disease we must consider certain facts about the development of tumours in animals. Following the application of tar to the skin there is a long latent period between the cessation of tarring and the appearance of tumours. A locally applied carcinogen may also act on a tissue remote from the scene of application; 60–80% of mice receiving tar application to the skin developed lung tumours (Murphy and Sturm 1925). Constitutional factors are important, and strains of mice especially sensitive to the action of polycyclic hydrocarbons can be bred. The successive actions of carcinogens are cumulative and also injury or non-specific irritation may precipitate tumour formation in a carcinogenically prepared field.

A number of substances are known to be carcinogenic and 9:10 dimethyl 1:2 benzanthracene is the most active hydrocarbon so far discovered. Amounts as small as 0·0004 mg. have produced sarcoma in mice (Shear 1936). A single intratracheal injection of 0·1 mg. methyl cholanthrene is followed by the development of multiple lung tumours in mice (Shimkin 1939). Active carcinogenic agents can be produced by heating a great number of substances to a temperature of 700°C—e.g., skin, yeast, voluntary muscle, and cholesterol. In a review of carcinogenic and anti-carcinogenic substances Dodds (1948) notes that there are a great many ways of producing cancer with no fundamental connections between them. He calls attention to objections to the accepted theory of a long-term action of carcinogenic substances.

If it is correct that the occurrence of carcinoma of the lung is increasing, the cause may be found in some factor or factors to which the general population has been more exposed in this century. For instance, the tarring of roads and the exhaust fumes of motor-cars have for many years been suggested as possible factors. The evidence, however, points to the disease being as prevalent among the general population in some wide open spaces—such as Western Canada,

SMOKING

An obvious possible factor in the causation of carcinoma of the lung is smoking. It has increased greatly in recent years, especially cigarette-smoking. Also there is still a sex difference, though it will be interesting to study this again after a sufficient lapse of time.

Roffo (1939) and Florey (1941) demonstrated that tobacco tar is carcinogenic in animals. Muller (1939) found suggestive evidence of smoking as a factor in an investigation of 86 patients with cancer of the lung; and in 1950 two large-scale inquiries were published. In America, Wynder and Graham (1950) questioned 605 men with carcinoma of the lung and found that 51·2% were excessive or chain smokers (more than 20 cigarettes per day for more than twenty years), compared with 19·1% in the general male hospital population without cancer. Only 1·3% of the cancer patients were non-smokers, compared with 4·6% of the non-cancer patients. They concluded that excessive and prolonged use of tobacco, especially cigarettes, seemed to be an important factor in the induction of carcinoma of the lung.

Doll and Hill (1950) published the findings on smoking which they obtained in the M.R.C. investigation referred to earlier. A carefully conducted inquiry with other cancer and non-cancer control groups, it is the most important contribution to our knowledge of this aspect of the ætiology of carcinoma of the lung yet published. Altogether 709 patients with carcinoma of the lung were interviewed—489 confirmed by necropsy, biopsy, or exploratory operation. Of the 649 men 0·3% and of the 60 women 31·7% were non-smokers. The corresponding figures for the non-cancer control groups were—men 4·2%, women 53·3%. Of the lung-cancer patients 26% of the men and 14·6% of the women who smoked gave as their most recent smoking habits, before their illness, the equivalent of 25 or more cigarettes a day; only 13·5% of the male, and none of the female non-cancer control patients smoked as much. Cigarette-smoking was more closely related to carcinoma of the lung than pipe-smoking. No distinct association was found with inhaling. They concluded that smoking was an important factor in the cause of carcinoma of the lung.

All the 300 patients interviewed in our series were asked the same questions:

1. The age-periods during which they had smoked.
2. The amount they habitually smoked before coming into hospital.
3. Details of their smoking history and the distinction between smoking pipes and cigarettes.

Soon after the investigation started it became apparent that many of the patients did not understand what was meant by inhaling, or else attached meanings to it different from the usual one of drawing some of the smoke into the lungs. To many it meant taking a very deep breath after drawing some smoke into the mouth and to a few it meant swallowing the smoke. As the investigation continued, we became more and more convinced that the answers we were receiving to this question were unreliable, and finally we gave up asking. It is our opinion that anyone who smokes cigarettes must inhale a certain amount of tobacco smoke, at least as far as the main bronchi.

The patients were placed in four groups according to their smoking history: non-smokers, cigarette-smokers, those who had only smoked pipes, and those who had smoked both a pipe and cigarettes. A non-smoker was defined as one who had never smoked more than an occasional cigarette at widely spaced intervals. Anyone smoking as much as one cigarette per day for three months would have been assessed as a smoker. In practice we found no difficulty, for all our 300 patients had either smoked for periods over two years or fell easily within our definition of a non-smoker. The cigarette-smokers were subdivided into heavy (more than 20 per day), medium (10–20 per day), and light (less than 10 per day), by estimating their average consumption over the years they had been smokers. This was not always easy, for many of the casual-labourer class smoke as many as they can afford, and so their consumption may vary from 2 per day when out of work, to 15 per day when working, or perhaps 30–40 per day during overseas military service. If they had been heavy smokers for a third of their smoking life, or for more than six years, they were allotted to that group. Several men over 50 had smoked heavily for three or four years during the first world war but since had been medium smokers; they were allotted to the medium group. By including both 10 per day and 20 per day in the medium group, that group has been enlarged, but we feel that thereby the heavy and light groups become more accurate and significant. Pipe-smokers were divided into heavy (more than 4 oz. per week), medium (2–4 oz. per week), and light (less than 2 oz. per week). Those who had smoked both pipe and cigarettes were subdivided into heavy, medium and light groups by taking into account only their cigarette-smoking and classifying them accordingly.

TABLE VI—NUMBERS OF SMOKERS AND NON-SMOKERS IN CANCER AND CONTROL GROUPS, WITH SEX-INCIDENCE

—	Non-smokers	Smokers	Probability test
Males			
Cancer (93)	5 (*5·4%*)	88 (*94·6%*)	$\chi^2 = 0{\cdot}0078$ $n = 1$ $P > 0{\cdot}0$
Control (186)	12 (*6·5%*)	174 (*93·5%*)	
Females			
Cancer (7)	4 (*57·1%*)	3 (*42·9%*)	Exact test $P > 0{\cdot}05$
Control (14)	11 (*78·6%*)	3 (*21·4%*)	

RESULTS OF SMOKING INQUIRY

Smokers and Non-smokers.—Of 100 cancer cases, 9 were classified as non-smokers. Of the 93 men, 5 (5·4%) were non-smokers, and of the 7 women 4 (57·1%) were non-smokers. The corresponding percentage in the 186 control men was 6·5 and in the 14 control women 78·6. These figures are shown in table VI.

Both sexes show no significant difference between the percentage of non-smokers in the cancer and control groups. In contrast Wynder and Graham (1950) and Doll and Hill (1950) found significant differences in the incidence of smoking in the cancer and control groups for both men and women, though this may perhaps be accounted for by the much larger samples which they used. It is of interest, however, to compare our figures with those of Doll and Hill, and this is done in table VII.

TABLE VII—COMPARISON OF SMOKING INCIDENCE IN MALE CANCER AND CONTROL GROUPS WITH THAT GIVEN BY DOLL AND HILL

—	Non-smokers	Smokers	Probability test
Cancer patients			
Doll and Hill (649)	2 (*0·3%*)	647 (*99·7%*)	$\chi^2 = 17{\cdot}26$ $n = 1$ $P < 0{\cdot}001$
Present series (93)	5 (*5·4%*)	88 (*94·6%*)	
Control patients			
Doll and Hill (649)	27 (*4·2%*)	622 (*95·8%*)	$\chi^2 = 1{\cdot}23$ $n = 1$ $0{\cdot}20 < P < 0{\cdot}30$
Present series (186)	12 (*6·5%*)	174 (*93·5%*)	

It will be seen that in the male cancer group Doll and Hill have found a significantly greater incidence of smoking than is suggested by our figures (99·7% compared with our figure of 94·6%). This difference in incidence of smoking is not found significant in the control group, where the corresponding figures are 95·8% and 93·5%. In the female patients, neither the cancer nor the control group show any significant difference in incidence: Doll and Hill gave 68·3% and 46·7% smokers for the cancer and control groups respectively, compared with our figures of 42·9% and 21·4% smokers.

The proportion of non-smokers in this series (9%) is higher than that found in previous series, and particularly so is the proportion in the males (5·4%). It was thought possible that some other factor might be at work in these patients, but a careful review of their histories did ot bring anything to light. 4 lived in suburban and in rural surroundings; 5 had no possible occupational actors; the other 4 had been exposed to cotton-dust, ailway fumes, mineral-oil, and flour. None had lived ear a gas-works or other industrial source of atmospheric ollution.

Type of Smoking.—The male and female patients ave been taken together for this comparison since, lthough few women smoke pipes, the proportion of women who are smokers is sufficiently small to make no ppreciable difference in the results. Of the 91 smokers in the cancer group, 68 (74·7%) were cigarette-smokers, 8 (8·8%) were pipe-smokers, and 15 (16·5%) smoked both a pipe and cigarettes. The 177 smokers in the control group contained 138 (78·0%) cigarette-smokers, 7 (4·0%) pipe-smokers, and 32 (18·0%) who smoked both. Table VIII shows the percentages of the different types of smokers, divided into age-groups; and it will be seen that there is a remarkable similarity in the percentages in the cancer and control groups. Doll and Hill, to distinguish between cigarette and pipe smoking, excluded those who had smoked both, and found that of the lung carcinoma patients who had smoked either pipes or cigarettes but not both, 5·7% were pipe-smokers compared with 9·7% in the corresponding section of the control patients. A similar comparison with our figures is given in table IX, and in contrast it will be seen that the percentage of pipe-smokers in the cancer group (10·5) is greater than that in the control group (4·8) though the difference is not significant.

TABLE VIII—PERCENTAGE OF CANCER AND CONTROL SMOKERS (MALE AND FEMALE) WHO SMOKE CIGARETTES OR PIPE OR BOTH, AND AGE-DISTRIBUTION. CONTROLS IN PARENTHESES

Age-group	Cigarettes	Pipe	Pipe and cigarettes
30–39 ..	5·5 (*6·8*)	0 (*0*)	2·2 (*0·6*)
40–49 ..	29·7 (*28·2*)	1·1 (*1·1*)	4·4 (*5·6*)
50–59 ..	25·3 (*28·2*)	5·5 (*1·1*)	3·3 (*7·3*)
60–69 ..	14·3 (*14·7*)	2·2 (*1·7*)	6·6 (*4·5*)
Total ..	74·7 (*78·0*)	8·8 (*4·0*)	16·5 (*18·0*)

Comparison of our figures for the incidence of pipe-smoking with those given by Doll and Hill reveals no significant differences, however. For the cancer patients $\chi^2 = 1{\cdot}85$, $n = 1$, $0{\cdot}10 < P < 0{\cdot}20$ and for the control patients $\chi^2 = 2{\cdot}77$, $n = 1$, $0{\cdot}05 < P < 0{\cdot}10$.

Amount Smoked.—The figures shown in table X were compiled according to our definition, given above, of heavy, medium, and light smokers. Considering the cigarette and pipe-and-cigarette smokers together as cigarette-smokers, we found that 38·5% of the cancer smokers were heavy cigarette-smokers compared with 23·2% of the control smokers. This difference is statistically significant $\chi^2 = 6{\cdot}19$, $n = 1$, $0{\cdot}01 < P < 0{\cdot}02$. Similarly only 7·7% of the cancer smokers are light cigarette-smokers, compared with 22·5% of the control smokers, and this difference is also statistically significant $\chi^2 = 8{\cdot}23$, $n = 1$, $0{\cdot}001 < P < 0{\cdot}01$.

TABLE IX—COMPARISON OF INCIDENCE OF PIPE-SMOKING IN CANCER AND CONTROL PATIENTS WHO SMOKE CIGARETTES OR A PIPE BUT NOT BOTH

—	Cigarette-smokers	Pipe-smokers	Probability test
Cancer (76) ..	68	8 (*10·5%*)	$\chi^2 = 1{\cdot}74$ $n = 1$ $0{\cdot}10 < P < 0{\cdot}20$
Control (145) ..	138	7 (*4·8%*)	

The numbers who smoke a pipe only, and the numbers who smoke a pipe and cigarettes are too small to make useful comparison between cancer and control of the amount of smoking done by each of these types of smokers. This has been done for the cigarette-only smokers in table XI, and the result is highly significant, indicating that the amount of smoking in the cancer group is larger than that in the control group.

This agrees with the conclusions of Doll and Hill, who, using 25 or more cigarettes per day as the definition of a heavy smoker, found 26% of lung carcinoma males fell into this category against 13% of non-cancer males.

Duration of Smoking.—The number of years during which the cancer and control smokers had smoked regularly is shown in table XII. In those patients who had smoked a pipe and cigarettes consecutively rather than concurrently, the total number of smoking years was used; thus the figures in the table do not differentiate between pipe and cigarette smoking. The numbers in the two lowest groups are small, but on combining these groups it will be seen that there is a significant difference between the cancer and the control smokers. This difference does not appear to be a simple one since there are more cancer than control smokers in the 20–29 group (50·5% against 32·2%) but less cancer than control smokers in the extreme groups (8·8% against 13% in the under-20 group, and 40·7% against 54·8% in the over-30 group).

The fact that the control patients had smoked for longer periods than those with lung carcinoma suggests that those who develop this disease may be more susceptible to any carcinogenic effect of smoking than normal people; but the difference is not enough for us to draw any definite conclusion.

Arsenic in Tobacco.—If smoking is a possible factor, it is interesting to note that tobacco smoke contains an appreciable quantity of arsenic.

Thomas and Collier (1945) have described a method of analysing the concentration of arsenic in tobacco smoke, employing combustion in the peroxide bomb, arsenic evolution, and titration of mercuric arsenide. The method of analysis attempts to simulate actual smoking

TABLE X—PERCENTAGE OF CANCER AND CONTROL SMOKERS WHO SMOKED CIGARETTES ONLY, A PIPE ONLY, AND A PIPE AND CIGARETTES, SUBDIVIDED BY AMOUNT SMOKED AND IN AGE-GROUPS

TABLE XII—NUMBERS OF CANCER AND CONTROL SMOKERS WHO HAD SMOKED FOR DIFFERENT LENGTHS OF TIME

—	Number of years of regular smoking					Probability test
	<10	10–19	20–29	30–39	> 40	
Cancer (91)	3 (*3·3%*)	5 (*5·5%*)	46 (*50·5%*)	21 (*23·1%*)	16 (*17·6%*)	$\chi^2 = 8·62$
Control (177)	4 (*2·3%*)	19 (*10·7%*)	57 (*32·2%*)	57 (*32·2%*)	40 (*22·6%*)	n = 3 (first two groups combined) $0·02 < P < 0·05$

conditions. They found that the smoke contained 11–23% of the arsenic on the average, the remainder being distributed between the ash and butts. The concentration of arsenious oxide in the puffed smoke was 0·2–3·0 mg. per cubic metre with cigars, 1·7–5·7 mg. with pipe tobacco, and 3·3–10·5 mg. with cigarettes. It appears that a third to half of the arsenic in tobacco may be found in the smoke.

Using a similar apparatus we arranged the following experiments.

Puffs of air, 10 ml. in volume, were drawn through the burning cigarette, each puff lasting $1^1/_2$ sec. with a 10 sec. interval between each puff. The puffed smoke was drawn through an electrostatic precipitator and the arsenic in the precipitated material determined. The arsenic content of the ash, the butts and the whole cigarette was also determined—the method used consisting of wet oxidation, distillation in the magnuson microstill and calorimetric estimation by the *molybdenum-blue method.*

The results are shown in table XIII.

It must also be noted that tobacco-smoke provides an additional source through which tarry substances of known carcinogenic quality may enter the respiratory system. Tobacco tar has been proved to be carcinogenic when applied to the skin. It would be interesting to know if there is an increased incidence of bronchial carcinoma in the tobacco industry. The operations in processing leaf tobacco are dusty and workers are exposed to lead arsenate, but according to McCormick and his colleagues (1948) the arsenic content of the dust is low (<0·095 mg./As/m³). Daff and Kennaway (1950), and Daff, Doll, and Kennaway (1951) have estimated the arsenic content of 27 brands of cigarettes. The results do not suggest that there is a relation between the arsenic content and the incidence of lung cancer in different countries.

TABLE XI—NUMBERS OF CANCER AND CONTROL SMOKERS WHO SMOKE ONLY CIGARETTES CLASSIFIED ACCORDING TO AMOUNT OF SMOKING

—	Heavy > 20	Medium 10–20	Light < 10	Probability test
Cancer (68)	30 (*44·1%*)	32 (*47·1%*)	6 (*8·8%*)	$\chi^2 = 11·54$
Control (138)	32 (*23·2%*)	76 (*55·1%*)	30 (*21·7%*)	n = 2 $0·001 < P < 0·01$

SUMMARY

Published work on the cause of cancer of the lung has been reviewed.

An investigation has been made into the environmental, occupational, and smoking history of 100 patients with carcinoma of the lung, living in the Liverpool area; 200 inpatients of the same age and sex, suffering from diseases other than cancer, were also interviewed. The 93 men and 7 women in the 100 studied were proven, by biopsy, necropsy, or operation, to have carcinoma of the lung.

Careful questioning showed that 47% of the cancer patients had been exposed appreciably to various dusts, fumes, and smokes; 43% of the controls had been similarly exposed, and in approximately the same proportions. Only a slightly higher proportion of the cancer patients lived in industrial areas (60% as compared with 54·5% of the controls). An equal proportion of the two groups (16–17%) had lived near a gas-works or other industrial source of atmospheric pollution.

No significant difference was found in the incidence of smoking, or of the proportion of cigarette-smokers, in the two groups. A significantly higher proportion (33·0%) of the cancer smokers had smoked more than 20 cigarettes per day than had the non-cancer smokers (18·1%). There was a slightly higher proportion of pipe-smokers among the smokers with cancer than among the smokers without cancer.

It is possible that heavy smoking of cigarettes may be a factor in the ætiology of carcinoma of the lung.

TABLE XIII—*DETERMINATION OF ARSENIC CONTENT OF CIGARETTES, AND OF THEIR SMOKE*

		Sample A	Sample B	Sample C
Portion of cigarette smoked ..		80–85%	80%	77%
Vol. of air drawn through cigarette, per g. of tobacco consumed ..		0·64 l.	0·69 l.	0·67 l.
Arsenic * in :	Puffed smoke ..	2·1, 2·5	1·7, 1·8	1·7, 1·9
	Ash	30·6, 26·0	19·6, 21·8	32·9, 32·4
	Butts	17·7, 16·8	10·8, 10·9	17·1, 15·6
	Whole cigarette ..	70·6, 64·4	38·3, 38·0	73·0, 70·0
Concentration in smoke—mg. As_2O_3/m^3		3·6	2·6	2·7

* Parts per million of As_2O_3 calculated on original weight of cigarette.

rom the Common Cold Research Unit, Harvard Hospital, Salisbury

THAT the common cold may be transmitted from man o man by the instillation into the nose of bacteria-free ltrates of infective nasal washings has been established y several workers and fully confirmed at the Common old Research Unit, Salisbury. This information, howver, throws little light upon the ways in which colds re transferred under natural conditions. The present eport is concerned with attempts to study the transission of colds under conditions closely resembling those f normal social intercourse.

EARLIER EXPERIMENTS

Earlier attempts to study the natural transmission of olds at this Unit had proved difficult. As already reported Andrewes 1949), 19 normal persons in one trial were xposed for ten hours to others with early colds, and nly one infection developed as a result; this was in a erson exposed to another in the presymptomatic ncubation period. In a second test none of 4 exposed eople, and in a third attempt only 1 of 5, caught colds. imilar difficulty in producing naturally transferred nfection was reported by Kerr and Lagen (1934).

In 1950 an experiment was made on an island off the orth coast of Scotland (Andrewes et al. 1951):

> The hope was that people conditioned by three months' omplete isolation would have acquired enhanced suscepti-bility and thus permit us to answer questions about the oute of transfer of infection. The possibility of transfer by means of droplet nuclei or by contamination of the environment was explored by much the same techniques as are described below. 12 people thus exposed to 10 people with profuse colds failed, to our surprise, to contract infection. The colds to which they were exposed were of one of our "pedigree strains"—i.e., one which had been artificially passed in series from one person to another by nasal instillation of stored washings. When later, in contrast to earlier failures, a natural or "wild" cold in a crofter did "jump" naturally to 3 of 8 of the exposed "islanders," we were led to consider the possibility that "wild" colds might have better powers of "jumping" than had the "pedigree" ones which had been used not only in the experiment on the island but also in all our previous tests at Salisbury.

We therefore decided to make more transmission experiments, using people with natural colds as "donors" of infection. In several trials we used children, since Lidwell and Sommerville (1951) have produced evidence indicating that they spread colds more readily than do adults.

EXPERIMENTAL METHODS

The organisation of the Common Cold Research Unit and methods used in experiments with human volunteers have already been described (Andrewes 1949). In the present experiments all the volunteers were examined clinically on arrival at the Unit and on each morning of their subsequent stay. On the day of arrival the volunteers were placed in isolation. Most of them were accommodated in pairs, but some remained in single isolation. Those who were passed as fit to take part in the experiments were all in good general health, aged, with three exceptions, 19–45, with a preponderance of females (141 females, 90 males).

Any volunteer showing signs of a cold during the first three days of observation was excluded from the experiment, and if the volunteer was one of a pair in isolation both were excluded. Those remaining free from signs of a cold on the morning of the third day after arrival were exposed later that day to possible risks of infection by the experimental procedures under investigation. Clinical observations of the volunteers in isolation were continued until the ninth day after arrival. Allocation to the experimental groups was made by the bacteriologist, using random sampling numbers. The nature of the exposure was not made known to the clinical observer until he had written up his assessments at the end of each experiment. In the final analysis of colds induced as a result of the procedures only those volunteers developing typical symptoms and signs subsequent to exposure have been recorded as having had colds. Those with doubtful signs, or subjective evidence alone, have been classified with those having had no colds.

People with "wild" or natural colds of recent onset have been selected as "donors."

Comparison of Transmission of Colds by Different Routes

The object of these experiments was to determine whether or not colds could be transmitted by droplet nuclei alone or by indirect contact alone, these conditions being compared with full exposure allowing all normal routes of transference to operate. Five similar experiments were made, involving 82 volunteers and 22 donors. The details of the procedure are described below; not every method was used in every trial.

Exposure to infected droplet nuclei.—A room of about 2000 c.ft. was divided into two with a blanket extending to within about 1 ft. of the side walls, floor, and ceiling. A fan ensured good mixing of the air throughout the whole chamber. 5 or 6 healthy volunteers sat on one side of the partition; they were asked to read or to sew quietly throughout the experiment. After a short interval to allow particles in the atmosphere to settle again, the donors and one observer, wearing sterile gowns to minimise the secondary release of infected particles from clothing, entered and sat on the other side of the partition. The donors were encouraged to play games involving talking, shouting, or singing but little bodily movement. Sneezing-powder (o-dianisidine hydrochloride) was liberated half-way through the experiment. A wide tube, connected to a slit-sampler operated outside the chamber, enabled the bacterial content of the air to be measured at intervals. The number of colonies of *Streptococcus salivarius* grown on a selective medium (Williams and Hirch 1949) was taken as an indication of the degree of contamination of the atmosphere by secretions from the respiratory tract. After a 2-hour exposure the donors left the transmission chamber, removed their gowns, and went to another room, of similar size but without a central division, for the second part of the experiment. The volunteers returned to their flats and remained in isolation until the end of the trial.

"*Full contact.*"—The conditions of exposure in this group were those of normal social contact. The same donors as in the first experiment mixed freely with a second party of healthy volunteers for a further period of two hours, eating luncheon together and later playing cards and other games. No bacterial samples of the air were taken in this room, but an observer again noted outstanding incidents, such as sneezing, coughing, and violent nose-blowing. At the conclusion of this experiment the donors departed and the volunteers returned to isolation.

Indirect contact in contaminated environment.—The third group of volunteers was next exposed to the environment which had been contaminated by the donors in the full-contact exposure. Playing-cards and other objects handled by the previous occupants were again used, and once more the period of exposure was two hours. Before the volunteers entered the contaminated environment, the room was aired for 10 minutes by opening windows and doors, to diminish the likelihood that infective particles would remain in the air.

RESULTS

The results of these experiments are summarised in table I. In three instances children aged 8–13 years acted as donors, and in two others adults were used. Two colds developed in 25 volunteers exposed to droplet infection, three in 32 exposed to full contact, and two in 25 exposed to a contaminated environment. The two colds in the last group were in volunteers occupying the same flat. One of these had minimal symptoms on arrival but remained clear during the quarantine period and was included in the trial. Symptoms returned on the day after exposure to the contaminated environment, and next day her partner showed signs of infection. Possibly a missed quarantine cold was responsible for both these infections; all the other colds shown in table I were separate incidents in different flats.

Another experiment is best considered separately; the results are not included in table I. Of 8 volunteers exposed to 5 children with colds 4 became infected. Conditions in this trial differed from those already described in two ways: the donors were, in part, younger children, their ages being 13, 11, 6, 5, and 4 years; also games were played, including blowing and nose-to-nose passing of a matchbox, rather a closer degree of contact, in fact, than is likely to operate commonly as a means of cross-infection. From all the experiments together we cannot conclude that children were more effective donors than adults.

Bacterial counts made during the droplet nuclei experiments indicated that there was considerable contamination of the atmosphere of the chamber with organisms from the respiratory tract, although the average for one trial was considerably lower than the other three. The number of colonies of *Strep. salivarius* per c.ft. of air sampled in one trial rose from an initial figure of 0·16 in the absence of children to 0·9 shortly after their entry, and to a peak of 3·2 per c.ft. immediately after the release of sneezing-powder. These figures are about twenty times as high as those found in recent trials in infants' school-rooms (Air Hygiene Committee of the Medical Research Council, personal communication).

TRANSMISSION BY MEANS OF MISTS

Since the results of exposure to infected droplet nuclei indicated that the common cold could spread by this means, studies were made with artificial mists of infected particles. In many instances material stored at −76°C in dry ice was used.

The apparatus consisted of a Collison-type spray, the metal parts of which were plated with gold. In the first two experiments power was supplied in the form of compressed air at a pressure of 10 lb. per sq. in., but it was found more satisfactory to use nitrogen from a cylinder at the same pressure. The droplet cloud was carried through a length of wide-bore rubber tubing to the nose-piece of a B.L.B. mask as used for the nasal administration of oxygen. When the source of power was nitrogen, a separate tube added pure oxygen to the inhaled vapour in the mask.

After the face-piece had been fitted and tested for leaks, the gas supplies were switched on, and the volunteer was instructed to inhale through the nose and to exhale through the mouth. A separate mask was used for each volunteer, and the virus suspension in the spraying chamber was changed after every 10 or 20 minutes' spraying. To reduce the inactivation due to the concentration of salt in the droplets, washings collected in 0·2% sodium chloride were selected in preference to those taken in physiological saline solution, and dilutions were made in distilled water. Protein, in the form of 0·2% bovine albumin, was also added to the spraying fluid. The true output of the spray under the conditions of the experiment was calculated to be 0·035 ml. per minute, and spraying for 5 minutes should deliver about the same dose of virus as that contained in 1 ml. of a 1 : 5 dilution of filtrate.

To investigate the possible effects of spraying on the infectivity of the material, the mist produced by the spray was drawn through 5 ml. of 10% broth-saline solution in a sampler containing small glass beads. After sampling for 5 or 10 minutes, the fluid was removed and the sampler was washed with a further 5 ml. of broth-saline solution. The spray sample was next tested in volunteers by the normal technique of inserting 0·5 ml. into each nostril in the form of drops.

As a further check on the output of the spray, and on the harmlessness of the process to a virus suspension, tests were made with influenza virus. Infected allantoic fluid from an A-prime strain A/Sweden/3/50 was diluted 10^{-4} in distilled water containing 0·2% bovine albumin and a small amount of radioactive iodine (I^{131}) was incorporated in the spraying mixture. The resultant mist was sampled in 10% saline solution, and the virus content of the original fluid and of the spray sample was determined by inoculating dilutions of both fluids into the allantoic cavity of developing 10-day hens' eggs. The dilution in the spray sample was estimated by measuring the radioactivity of both fluids with a Geiger counter. The results indicated that there had been no appreciable inactivation of influenza virus by spraying. It would, of course, be unwise to assume that the common cold virus is as stable as that of influenza.

TABLE II—SUMMARY OF SPRAYING TESTS

Test	Serial nos. of trials	Colds induced	No colds induced	No. of volunteers	Percentage positive
Spray $^1/_2$ minute ..	114, 115, 116	3	13	16	20·0
Spray 3 or 5 minutes	114, 115, 120	4	11	15	26·7
Spray collected and given as drops ..	116, 120, 121	4	16	20	20·0
Drops 1 : 5 or 1 : 10	114, 115	4	4	8	50·0
Drops 1 : 50 or 1 : 100	114, 115, 116, 120, 121	11	19	30	36·7

The results of the spraying tests are shown in table II, which shows that the common-cold virus can survive the spraying, and that a cloud of infected droplets will produce colds in some of the persons exposed. The figures suggest, however, that the same volume of material was less effective as spray than as drops; they are not, however, highly significant (P=0·07).

CONTAMINATION OF EXTERIOR OF NOSE

Three experiments were made in which infective secretions were applied only to the outside of the nose.

TABLE I—SUMMARY OF CONTACT EXPERIMENTS

Trial no.	Date of exposure (1951)	Donors	Droplet nuclei					Full contact			Contaminated environment

126	Dec. 12, 1951	Virus painted around external nares	..	0	7	7	Material produced 6 colds in 10 volunteers in trial no. 123
		Virus administered as drops.. ..	..	0	4	4	

No colds developed in 22 volunteers so exposed. The details of the experiments are as follows:

(1) Sterile cotton-wool swabs mounted on wooden applicators were soaked in infected material, and about 0·1 ml. was painted on the skin round the external nares. The 7 volunteers so treated were instructed not to touch or to wipe the nose for an hour after this procedure. Four volunteers received 1 ml. of a 1 : 10 dilution of the same material by the usual dropping technique. No colds resulted in either group, although the material, a filtrate of infected washings from a young adult with a "wild" cold, had previously produced six colds in 10 volunteers.

(2) Nasal blowings from 5 adults with recent colds were collected on 'Cellophane' handkerchiefs. These were washed off with 10% saline solution, and the pool of about 15 ml. of crude material was shaken with glass beads and then centrifuged to remove gross debris. The opalescent supernatant fluid was distributed in 1 ml. quantities, on the centre of clean linen handkerchiefs, which were refolded and issued to 8 healthy volunteers. Each volunteer was instructed to blow the nose on the contaminated handkerchief immediately, and to use the handkerchief throughout the succeeding twenty-four hours. The interval between contamination of the handkerchiefs and their first use by the volunteers was usually about half an hour, during which time most had dried sufficiently to be passed as clean handkerchiefs by the volunteers using them. No colds developed as a result of this procedure, although there were two colds in 7 other volunteers who were exposed to the 5 donors of the infected secretions for two hours under conditions of full contact.

(3) Eight-inch squares of sterile gauze, folded into pads eight layers thick, were contaminated by dropping 0·5 ml. of undiluted nasal washing into the centre of each. The impregnated pads were immediately handed to volunteers, who were instructed to spread the contents of the gauze over the outside of the nares and to repeat the process at short intervals for an hour, during which time they were neither to wash the hands nor to blow the nose. Concurrently 8 other volunteers received the same material, diluted 1 : 2 in broth-saline solution, by the usual dropping technique, and a third group of 7 volunteers was infected by means of packs inserted into the nose (see below). No colds developed in the 7 volunteers who applied the material to the outside of the nose, whereas 5 out of 8 receiving drops developed colds, and two colds developed in the third group.

It thus appears that the placing of infective secretions round the outside of the nose is unlikely to produce a cold. The absence of colds in the group of volunteers using contaminated handkerchiefs for twenty-four hours was unexpected. The result suggested that the virus might be particularly sensitive to drying. To test this hypothesis infective secretions were allowed to dry on gauze before being used for transmission studies.

COMPARISON OF MOIST AND DRY PACKS INSERTED INTO NOSE

Sterile ribbon-gauze strips 12 in. in length were soaked in 0·25 ml. of material known to be infective. Each strip was then kept over calcium chloride in a sealed container at room-temperature for an hour, after which the packs appeared to be quite dry. A second series of gauze strips was impregnated with the same amount of material shortly before the time of insertions. Volunteers were allocated in random fashion to one of two groups, and the appropriate gauze strip was inserted into one nostril with a sterile wooden applicator and remained in position for two hours. The results of this experiment are shown in table III. There were no colds in 10 volunteers exposed to infection by dry packs, and two colds among 9 exposed to moist packs. The numbers do not permit a statistical comparison of the two methods, but suggest that there has been inactivation of the virus as a result of the drying.

DISCUSSION

An analysis of the results in this Unit has shown that an average of 50% of volunteers may be expected to develop colds after the instillation of infected drops into the nose, irrespective of age, frequency of natural colds, or time since last cold. Though individual susceptibility varies considerably, the sensitivity of a group of 6–8 volunteers to infection with a given strain of virus may be expected to be rather more constant. Wherever possible such numbers have been used; otherwise duplicate experiments have been made on smaller groups.

Standardisation of the dose of infective material in transmission studies presents much greater difficulties. Although donors were selected on a history of recent onset of symptoms, together with nasal obstruction and discharge, it was impossible to assess the amount of secretion disseminated by different people other than by a crude estimate based upon direct observation. By using groups of 4 or 5 donors it was hoped that the effects of this variation might be lessened. As seen in table I, two groups of donors failed to pass their colds on by any route. In one of these the observer reported that the children acting as donors were quiet throughout the experiment, and this is reflected in the low figure for aerial contamination in this group. In the other trial no colds developed after exposure to 5 adults, although the plate counts indicated a considerable degree of contamination of the atmosphere.

With such a low rate of positives comparison between the three groups is clearly unjustifiable. There is *definite* evidence that colds may pass from person to person as a result of normal social contact, and that exposure only to infected droplet nuclei will produce colds in a small proportion of those exposed. The evidence for spread by indirect contact is, as explained above, less convincing, and further experiments are needed before the importance of this route can be estimated.

The fact that colds did develop as a result of droplet spread, in spite of the relatively small amount of material which can have reached the noses of the recipients, suggested that experimental infection of volunteers with a given quantity of virus might be more readily achieved by exposure to infected droplets than by other methods.

Comparative tests were therefore made with artificial droplet mists. Using strong virus suspensions we could induce colds in about 1 in 5 of persons inhaling the ærosol for $^{1}/_{2}$–5 minutes. When, however, about the same dose of virus was introduced into the nose in the form of drops, the rate of "takes" rose to 1 in 3 or 1 in 2. Experimentally, therefore, it appeared that infection by means of mists was a less effective method of inducing colds in volunteers than our customary method of applying drops to the nose. The technique has the further disadvantages of requiring more complicated apparatus, and of using much greater quantities of virus.

The transmission of any agent by indirect contact involves three stages. The environment must first be contaminated by an infected subject, the secretions must be in a state in which they retain their infectivity, and they must be picked up by a susceptible person and transferred by him to the nose. If we apply these ideas to our trials with the common cold, the available evidence suggests that infected secretions are rapidly inactivated by drying. Further, even when the route of transmission has been shortened to the extent of applying material of known infectivity to the outside of the nose, no colds have resulted.

Experiments made earlier, with fluorescent dyes used as tracers, had shown how readily secretions could be passed directly and indirectly from one person to another (J. E. Lovelock and K. R. Dumbell, personal communication). The present results do not support the idea that this transfer is necessarily effective, and indeed suggest that indirect contact is unlikely to play a major part in the spread of the common cold. Our tentative conclusions apparently conflict with a statement which has been made on several occasions: Arctic explorers are reported to develop colds when undoing bales of clothing which have been kept packed up for many months. The implication is that the agent concerned is very stable. One must assume either that their symptoms were due to something other than the common cold, or that their isolation had conditioned them to respond to very small doses of virus. In the present experiments "takes" as a result of direct contact compare not unfavourably with the natural rate of cross-infection in homes (cf. Lidwell and Sommerville 1951); that they are rather fewer is not surprising in view of the fact that in our experiments there was a single period of exposure, whereas in the observations of Lidwell and Sommerville contact was for some days.

The question discussed here is important. We are very conscious that the low incidence of colds induced as a result of our experiments has meant that our findings are much less conclusive than we could have wished. It is probably true that the development of an overt cold in man is determined more by the varying susceptibility of the person than by the degree of exposure to the causal agent.

CONCLUSIONS

Though common-cold infection may spread from person to person by normal social contact, and through the air in the form of droplet nuclei, the rate of clinical cross-infection is low.

We found no evidence suggesting that spread by indirect contact is of major importance in the natural transmission of the common cold.

Our results suggest that the virus of common cold may be sensitive to drying.

FURTHER INVESTIGATION INTO CAUSES OF THROMBOPHLEBITIS FOLLOWING INTRAVENOUS INFUSIONS

PHARMACIST, UNIVERSITY COLLEGE HOSPITAL

In a previous paper (Bolton Carter 1951) it was shown that the incidence of thrombophlebitis resulting from intravenous infusions could be diminished by limiting the duration of infusion to eight hours.

So far as practicable this procedure has been followed with all infusions set up in the surgical unit of University College Hospital over the last two years. During this period there has been no case of thrombophlebitis severe enough to cause the patient gross discomfort.

All the infusions have been carefully followed up, with inspection of the infusion sites, for a week afterwards, and all cases showing $^{1}/_{2}$ in. of venous thrombosis with $^{1}/_{2}$ in. of surrounding inflammation, or more, have been recorded as cases of thrombophlebitis.

From January, 1951, to August, 1951, the results were:

Infusions running for less than eight hours:
121
15
Infusions r hours:
3 produced no reaction.
7 " thrombophlebitis.

Thus 11% of the infusions running for less than eight hours produced thrombophlebitis.

All of these infusions consisted in some part of 5% dextrose. Since solutions of dextrose when autoclaved become acid, it was decided, as the next step in the investigation of infusion thromphlebitis, to study this factor. For three months the pH of every bottle of infusion fluid was measured electrometrically with a glass electrode, and it was found that the pH of whole citrated blood and of physiological saline solution was reasonably constant, being slightly on the acid side of normality, whereas that of the dextrose solution varied between 3·1 and 5·8, averaging 4·5. Having established that the dextrose solution was the only infusion fluid with an unstable and acid pH, a trial of buffered dextrose with a stable pH was started.

BUFFERED DEXTROSE

Previous work had shown some of the difficulties of buffering dextrose. Hudson and Tarlowski (1947) and Bryan and Grainger (1950) found that the addition of sufficient phosphate buffer to prevent the pH falling below 6 caused so much caramelisation as to render the solution unfit for use. Other methods tried by these workers are either impracticable or have the disadvantage of causing auto-agglutination and hæmolysis *in vitro*.

We have tested the effect of 0·2% and 0·5% of disodium hydrogen phosphate and 0·5% of trisodium citrate as buffers for 5% dextrose, and found the latter to give consistently a slightly higher pH. Such buffered solutions, however, have a well-marked brown colour due to caramelisation.

Since sodium metabisulphite has proved useful as an antoxidant in several injections, its effect was tested in preventing the darkening of buffered dextrose solutions. It was found that in concentration of 0·01% the colour was reduced from dark brown to pale yellow, and that with 0·1% the solutions were almost colourless or at the most pale yellow.

Although the dark-brown solutions have generally been regarded as unfit for use and pharmaceutically are unsatisfactory, there seem to be no references to clinical tests on such coloured solutions. Previous experience has led us to conclude that the coloration is not harmful. In testing the effects of buffered dextrose solutions, therefore, it was decided to try two types of solution, one coloured by caramelisation, and the other with the factor controlled, to see if the incidence of thrombophlebitis would be reduced. The following solutions were used:

(1) 5% dextrose with 0·5% sodium phosphate; after autoclaving this was deep brown and had a pH of 5·56.

(2) 5% dextrose, 0·5% sodium citrate, and 0·1% sodium metabisulphite; after autoclaving this was almost colourless and had a pH of 6·05.

Although sodium metabisulphite tends to lower the pH slightly, this is more than offset by its action in preventing oxidation of dextrose and consequent increase in acidity.

In preparing solution (2) some difficulty was encountered with the effect of citrate in causing flaking of glass in transfusion bottles, but this was overcome by washing with acid and rinsing thoroughly before use.

Results

From August to November, 1951, when the pH of all infusions was being estimated and unbuffered dextrose was used, the results were:

Infusions running for less than eight hours:
88 produced no reaction.
18 ,, thrombophlebitis.
Infusions running for more than eight hours:
14 produced no reaction.
5 ,, thrombophlebitis.

Thus 17% of infusions running for less than eight hours produced thrombophlebitis.

From November, 1951, to February, 1952, the 5% dextrose solution was buffered as described above, and in this period the pH of all bottles of infusion fluids was estimated and in all cases approximated to normal. The results in this series were:

Infusions running for less than eight hours:
109 produced no reaction.
23 ,, thrombophlebitis.
Infusions running for more than eight hours:
10 produced no reaction.
7 ,, thrombophlebitis.

Thus 17·5% of infusions running for less than eight hours produced thrombophlebitis.

The incidence of thrombophlebitis had not, therefore, been lessened by buffering the dextrose.

There were no clinical signs of toxicity from the buffered dextrose, and no difference was noted between the effects of the coloured solutions and those of the colourless solutions.

Since the institution of the eight-hour limit for infusions no case of severe thrombophlebitis has been seen in the wards of the surgical unit.

SUMMARY

In order to see if the incidence of thrombophlebitis resulting from intravenous infusions could be reduced the 5% dextrose solution used for infusion was buffered with either 0·5% sodium phosphate or 0·5% sodium citrate and 0·1% sodium metabisulphite, thereby approximating its pH to that of normal blood.

There were no toxic reactions to the buffered dextrose, but the incidence of thrombophlebitis was unchanged.

The importance of the time-factor, if the incidence and severity of thrombophlebitis is to be reduced, is confirmed.

This investigation was carried out under the guidance of Prof. R. S. Pilcher, and much of the work was done by Messrs. J. M. Doyle, A. W. Johnston, J. L. Somervell, and P. K. Thomas, house-surgeons on the Surgical Unit when the investigation was in progress.

HEPATIC CHOLESTEROL CONTENT IN NUTRITIONAL DISORDERS

V. Ramalingaswami

An increase in total cholesterol of liver, mainly due to the esterified fraction, is known to occur in various types of fatty livers produced experimentally in animals by dietary means.

In the so-called "fat" fatty liver of choline deficiency resulting from the feeding of high-fat low-protein diets to rats a small but definite increase in the cholesteryl-ester content was reported by several workers (Best et al. 1934, Channon and Wilkinson 1936, Ridout et al. 1946, Gajdos 1951).

In the fatty liver of depancreatised dogs maintained with insulin a considerable increase in the cholesteryl-ester fraction was noted, although triglycerides accounted for the major part of the accumulated lipids in the liver (Kaplan and Chaikoff 1937).

The most striking increase in the cholesteryl-ester content of the liver was found in the severe fatty livers produced in rats by feeding cholesterol in the diet (Okey 1933, Chanutin and Ludewig 1933, Best et al. 1934).

Gavin and McHenry (1941) reported that fatty livers characterised by the accumulation of large amounts of cholesterol were found in rats given biotin, and that this type of fatty liver was resistant to the action of choline but could be prevented with inositol. However, Best et al. (1946) were unable to confirm these findings.

Although there is experimental evidence that cholesterol accumulates in fatty livers of dietary origin in animals, it is not known whether a similar accumulation of cholesterol occurs in human fatty livers of nutritional origin. Severe fatty infiltration of the liver, almost certainly due to malnutrition, is common in kwashiorkor (infantile pellagra, malignant malnutrition) which was first adequately described by Williams (1933) in West Africa and later studied in greater detail in Africa and the West Indies. This disease, with all its characteristic features, occurs in India (Ramalingaswami et al. 1948) and is called "nutritional œdema syndrome" by Gopalan and Patwardhan (1951). In these laboratories we also have found fatty infiltration of the liver in adults with nutritional œdema (unpublished observations). We report here our findings on the cholesterol content of the liver in 6 children with kwashiorkor and 6 adults with nutritional œdema.

TABLE I—FATTY INFILTRATION AND CHOLESTEROL IN LIVER BIOPSY SPECIMENS

Case no.	Age (yr.)	Sex	Fatty infiltration	Anisotropic material	Cholesterol content (% of weight of dry tissue)
Kwashiorkor:

16	35	M	45·33	1·777	3·9	+ + + +	Nil
17	40	M	13·01	1·422	10·4	+	Nil

PRESENT OBSERVATIONS

Our attention was first drawn to the cholesterol component of the liver lipids in these conditions by the observation that, in some sections of liver biopsy specimens stained for fat with Sudan IV, a crystalline material in the form of flat plates with notched edges and needles was present inside the fat globules. The crystals stained poorly with Sudan IV. They were absent in sections from the same livers which were exposed to alcohol and xylene. The fact that they were doubly refractile under polarised light made us suspect that they might be cholesterol. The biopsy specimens, fixed in neutral formalin, were subjected to quantitative chemical estimation of cholesterol by the Liebermann-Burchard reaction. The results are given in table I. Because of the small size of the biopsy specimens it was impossible to estimate any lipid fraction other than total cholesterol. In a few cases coming to necropsy, however, the total lipids were also estimated; the results are given in table II. The severity of fatty infiltration of the livers was graded arbitrarily as 0 to + + + + on examination of Sudan-stained sections. The amount of anisotropic material in the sections was also graded in a similar manner on examination of the sections under polarised light. It will be seen from the tables that, in the livers in which chemical estimations were possible, there is moderate to considerable increase in the cholesterol content. Case 2, whose liver contained the greatest amount of anisotropic material (fig. 1), also showed the highest cholesterol value. Another liver biopsy specimen from the same case, after four weeks' treatment with skimmed-milk powder, showed almost complete disappearance of anisotropic material (fig. 2). The specimen also showed a striking reduction in the amount of sudanophilic material.

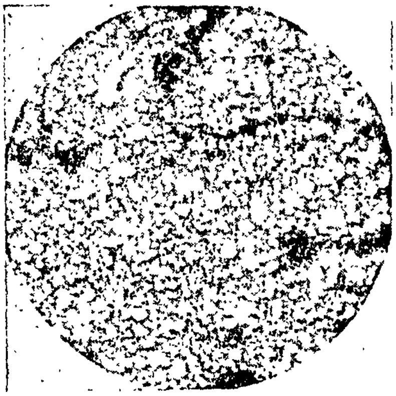

Fig. 1—Biopsy specimen of liver (case 2) under polarised light, showing large amounts of anisotropic material (× 70).

DISCUSSION

The pathogenesis of accumulation of cholesterol in the livers is not quite clear. The accumulation of cholesterol is accompanied in all cases by large amounts of Sudan-stained droplets, which are presumably neutral fat. This seems to resemble the accumulation of cholesterol in the "fat" fatty liver of choline deficiency in rats, in which the deficient formation of lecithin would be expected to lead to an accumulation of cholesteryl esters for lack of recipients for their fatty acids (Peters and Van Slyke 1946). Our observations, however, show that there is no direct correlation between the amount of cholesterol and the severity of fatty infiltration assessed histologically or chemically. They suggest that the accumulation of cholesterol is not merely incidental to the accumulation of neutral fat, and that a specific disturbance of cholesterol metabolism might be involved. It has been reported that the pancreatic factor, lipocaic, has a specific preventive effect on the deposition of cholesterol in the liver in animals (McHenry and Patterson 1944), and it is perhaps significant that extreme atrophy of pancreatic acini is characteristic of kwashiorkor (Waterlow 1948, Davies 1948). Our preliminary observations indicate that, on treatment with skimmed-milk powder, there is a regression of cholesterol together with neutral fat. The precise factors responsible for this effect are now being studied.

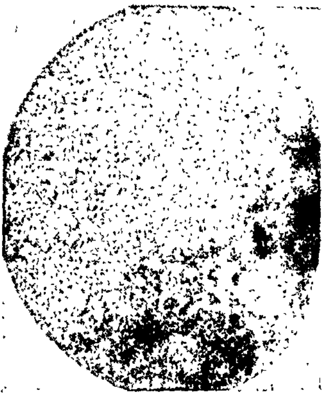

Fig. 2—Biopsy specimen of liver (case 2 after treatment) under polarised light, showing considerable decrease of anisotropic material (× 70).

SUMMARY

A considerable increase in the cholesterol content of livers was found in some cases of kwashiorkor and nutritional œdema in adults. The significance of this finding is discussed.

We wish to thank Sir Harold Himsworth for his most valuable comments, and our colleagues in the Nutrition Clinic for the supply of clinical material.

"... Our bad habit of polluting the air with waste products of combustion and other chemical processes was formed long ago, but since the beginning of the industrial revolution a minor irritation has become a great social evil. In towns and industrial districts rain water loses its purity: ash and other solids fall continuously to the ground; the air contains a suspension of fine particles which penetrate indoors, to be deposited on walls, ceilings, curtains, and furniture; our clothing, our skins, and our lungs are contaminated; metals corrode, buildings decay, and textiles wear out; vegetation is stunted and blackened; sunlight is lost; germs multiply; our natural resistance to disease is lowered. In a hundred and one ways the miasma of atmospheric pollution is lowering our vitality and our enjoyment of life. . . . We cherish our freedom to do as we please in our homes, but just as we no longer throw rubbish into the street, we shall eventually cease to discharge smoke into the air."—A. R. MEETHAM, D.SC., *Atmospheric Pollution*. London: Pergamon Press, 1952; p. 5.

THE EFFECT OF CORTISONE ACETATE ON ADRENAL ASCORBIC-ACID DEPLETION FOLLOWING STRESS

DENIS ABELSON
M.D. Lond., M.R.C.P.
REGISTRAR, THE MEDICAL UNIT, MIDDLESEX HOSPITAL, LONDON

D. N. BARON
M.D. Lond.
SENIOR LECTURER IN CLINICAL BIOCHEMISTRY, S. A. COURTAULD INSTITUTE OF BIOCHEMISTRY, MIDDLESEX HOSPITAL MEDICAL SCHOOL, LONDON

Sayers and Sayers (1947) showed that the depletion of adrenal ascorbic acid following various stresses could be abolished by prior administration of adrenal cortical extract. Of the crystalline steroids which they also tested, 17-hydroxy,11-dehydrocorticosterone (cortisone) and 17-hydroxycorticosterone were the most potent in this respect, followed in order by corticosterone, deoxycortone, and progesterone, the last exerting only a small effect. Gray and Munson (1951) obtained similar results with adrenal cortical extracts, but Fortier et al. (1951), using both free cortisone and cortisone acetate, could not substantiate the findings of Sayers and Sayers (1947).

In view of these conflicting reports, it seemed desirable to investigate the problem further in relation to cortisone acetate, and to determine if a relationship existed between dose and response.

METHOD

Male white Wistar rats were used, with an average weight of 150 g. (range 142–156 g.). Controls were killed by stunning followed by decapitation; both adrenals were then removed. Cortisone acetate (Merck) was centrifuged, washed free from suspending medium, and resuspended in physiological saline to the required concentration. In the first two experiments, the left adrenal was removed under ether anæsthesia two hours after the intraperitoneal injection of cortisone, and an hour later the rat was killed and the right adrenal removed. In the third experiment adrenocorticotropic hormone (A.C.T.H.) was administered intravenously two hours after the intraperitoneal injection of cortisone, and both adrenals were removed an hour after this. To minimise the stress of intraperitoneal injections of cortisone, saline rather than alcoholic preparations were preferred, administered in volumes of 0·2 ml. The adrenals were crushed with a glass rod in test-tubes each containing 2 ml. of 4% trichloracetic acid and a little sand. The rod and sides of the tube were washed with 3 ml. of trichloracetic acid, and about 75 mg. of acid-washed charcoal was added (it was found that large quantities of charcoal interfered with the recovery of ascorbic acid). After filtration the ascorbic-acid content of the filtrate was estimated by the method of Roe and Kuether (1943), with the following modifications:

TABLE I—EFFECT OF SALINE AND CORTISONE ON STRESS-INDUCED ASCORBIC-ACID DEPLETION

Experiment	No. of rats	Mean level of adrenal ascorbic acid (μg. per 100 mg.) ±S.E.		
		Left	Right	Difference
Controls ..	10	235 ±12	213 ±12	−22 ±13 (P> 0·1)
Saline	9	261 ±12	164 ±14	−97 ±12 (P < 0·01)
Cortisone ..	10	210 ±12	179 ±14	−31 ±14 (P> 0·05)
Comparison of means:				
Controls and saline ..		P> 0·1	—	P < 0·001
Saline and cortisone ..		P <0·01	—	P <0·01
Controls and cortisone		P> 0·1	—	P> 0·6

(1) The thiourea was made up in water instead of 50% ethanol. This prevents the turbidity (due probably to the formation of ethyl trichloracetate) which sometimes appears after the sulphuric acid is added.

(2) It was found simpler to mix the solutions of thiourea and 2 : 4-dinitrophenylhydrazine (1 : 5) before use than to add the reagents separately. This combined reagent keeps in the refrigerator for several weeks, but requires filtering before use.

(3) To 3 ml. of adrenal filtrate 1·5 ml. of colour reagent was added, and the tube was incubated at 70°C for 30 minutes. After cooling, 2 ml. of concentrated sulphuric acid was added. The colour intensity was determined with a Spekker absorptiometer using a 604 (Ilford) filter which transmits maximally at 520 mμ.

TABLE II—EFFECT OF CORTISONE AT DIFFERENT DOSE LEVELS ON STRESS-INDUCED ADRENAL ASCORBIC-ACID DEPLETION

Dose of cortisone (mg.)	No. of rats	Mean level of adrenal ascorbic acid (μg. per 100 mg.) ±S.E.		
		Left	Right	Difference
0	10	192 ±16	135 ±11	−57 ±13
2·5	10	181 ±9	153 ±7	−28 ±10
5·0	10	192 ±8	180 ±19	−12 ±18
10·0	9	185 ±14	175 ±13	−10 ±16
20·0	8	197 ±14	222 ±20	+25 ±14

Analysis of variance

Source of variance	Degrees of freedom	Sum of squares	Mean square	Variance ratio	P
Between doses:					
Due to regression ..	1	27,565	27,565	14·0	<0·001
Departure from regression ..	3	4084	1361	0·7	> 0·1
Within doses ..	42	82,849	1973	—	—
Total ..	46	114,498	2489	—	—

S.D. within doses = 44·4. b ±S.E. = 3·6 ±0·95.

RESULTS

Table I shows a comparison between a group of control rats, a group receiving saline and a group receiving cortisone. There was no significant difference between the ascorbic-acid concentrations of the left and right adrenals in the controls. After the injection of saline followed by left adrenalectomy there was a considerable fall in ascorbic-acid concentration in the right adrenal an hour later. This fall did not take place in the group pretreated with cortisone. There was, however, some difference between the mean initial levels of ascorbic acid, and the experiment was therefore repeated, the groups being stratified with respect to weight, and doses of 2·5, 5, 10, and 20 mg. of cortisone being used. The results are set out in table II. In this experiment there was no significant difference between the mean values for the left adrenal, and the inhibition of the stress response

TABLE III—COMPARISON OF EFFECTS OF A.C.T.H. AND SALINE (ADMINISTERED INTRAVENOUSLY UNDER ETHER ANÆSTHESIA) IN RATS PRETREATED WITH CORTISONE

Experiment*		No. of rats	Mean level of adrenal ascorbic acid† (μg. per 100 mg.) ±S.E.	Comparison of means
Pretreatment (intraperitoneal)	I.V. injection 2 hr. after pretreatment			
Saline	Saline	5	189 ±11	P <0·01
Cortisone 20 mg.	Saline	5	260 ±14	P <0·05
	A.C.T.H. 0·6 μg. in saline	5	211 ±12	

* Each injection was made up in a volume of 0·2 ml.
† In this experiment both adrenals were removed together an hour after the intravenous injection.

is clearly shown. It will also be seen that, over the dose range used, there was no evidence against a linear relationship between degree of inhibition and dose.

In accordance with the work of Sayers and Sayers (1947) we have also found that, in rats pretreated with cortisone, adrenal ascorbic-acid depletion still occurs after the administration of A.C.T.H. (see table III).

During the investigation, which extended from August, 1951, to May, 1952, the adrenal glands were found to be heavier in the winter. The cause of this is unexplained.

A few minutes after the injection of cortisone the rats became sleepy. This hypnotic effect has previously been noted (Selye and Stone 1944).

DISCUSSION

A notable feature of the results is the large dose of cortisone required to abolish the stress response. Sayers and Sayers (1947) found that 200 µg. per 100 g. of body-weight prevented the depletion of ascorbic acid that otherwise follows the administration of histamine (0·5 mg. per 100 g. of body-weight).

Further work will be required to establish the specificity of cortisone in this reaction, and to define the precise mechanisms involved. The fact that A.C.T.H. still produces a depletion of adrenal ascorbic acid in rats pretreated with cortisone suggests that cortisone acts not by neutralising A.C.T.H. in the peripheral blood or tissues, but by depressing the output of A.C.T.H. from the anterior lobe of the pituitary gland. It is not yet possible to state, however, to what extent the release of A.C.T.H. from the pituitary under physiological conditions depends on the level of circulating adrenal cortical steroids.

The method described might provide a basis for the assay of A.C.T.H., rats pretreated with cortisone being used instead of hypophysectomised rats.

SUMMARY

The depletion of adrenal ascorbic acid following unilateral *adrenalectomy* in rats can be inhibited by *prior administration* of cortisone intraperitoneally.

Over the dose range tested there was no evidence *against a linear relationship between degree of inhibition* and dose.

A.C.T.H. still causes depletion of adrenal ascorbic acid in rats pretreated with cortisone.

We are indebted to Prof. E. C. Dodds and Prof. A. Kekwick for their advice, and for affording facilities; Mrs. S. A. Simpson for invaluable help at all stages of the work; Dr. B. Clayton and Dr. I. C. Gilliland for helpful suggestions; Dr. P. Armitage for statistical aid; and Miss H. Grundy and Mr. S. Graves for technical assistance. Cortisone acetate (Merck) and A.C.T.H. (Armour) were generously provided through the Medical Research Council.

New Inventions

IMPROVED ILIAC-CREST SUPPORTS

THE use of iliac-crest (pelvic) supports has been largely neglected by surgeons who use the Trendelenburg position. In place of iliac-crest supports they use shoulder-rests and flexion of the legs over the end of the operating-table. These are both bad—brachial palsy is likely from one[1] and calf and popliteal thrombosis from the other—and it is difficult to adjust the table "break" to coincide with the knee-joints.

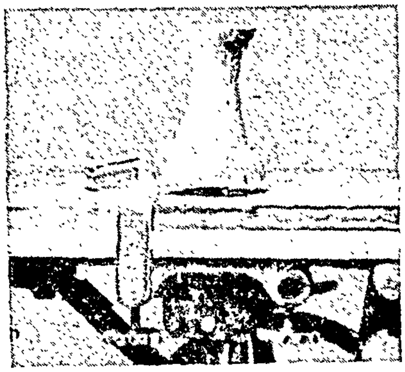

Fig. 1.

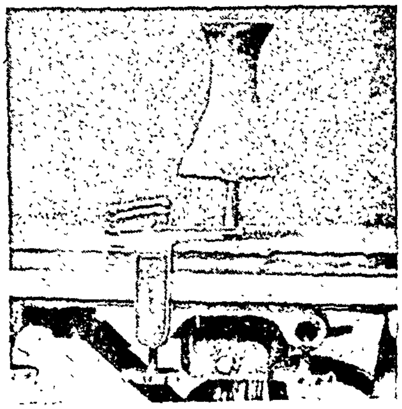

Fig. 2.

Ogier Ward[2] describes the use of his supports, but points out that it requires a little experience by a theatre technician to adjust them properly. In addition, they are of fixed height and may obstruct the surgeon. The rubber faces also tend to twist off and upset the mechanics of the supports.

The new supports described here are more efficient and easier to use because (1) the shape will fit any normal iliac crest; (2) the support rotates freely round a vertical axis and always presents a correct bearing surface for the iliac crest; and (3) the support can be raised or lowered to fit any iliac crest and keep out of the way of the surgeon (figs. 1 and 2).

These supports can be fitted to the standard Ogier Ward supports. In use they are largely self-adjusting, and their application is straightforward. They are initially applied to the waist of the patient and, as tilting takes place, the iliac crests move downwards into contact with them (fig. 3).

Reviews of Books

Medical History of the Second World War

Editor-in-Chief: Sir ARTHUR MACNALTY, F.R.C.P. Vol. I. *Medicine and Pathology.* Editor: V. ZACHARY COPE, M.D., F.R.C.S. London: H.M. Stationery Office. 1952. Pp. 565. 50*s.*

THIS is the first of eighteen volumes designed to record the history of military and civil medicine in the late war. (The whole will be but part of the Official History of the War, which judging by that of the war of 1914–18, is not likely to be finished for some time.) It is made up of signed contributions by many distinguished authors whose ability to make bare facts and sombre figures readable is apparent and welcome. Any doctor, however specialised his interests, can read most of this book with interest and benefit. That there is so little overlapping by the contributors is no doubt due to editorial skill; but the prospectus of the volumes now in preparation suggests that it will be hard to avoid this difficulty throughout.

The book begins with general reviews of the medical problems of the three Services and of the civil population in war. Each approaches the subject in an individual way, and each is admirable—an adjective which may also be applied to Desmond Curran's review of naval psychiatry. Some of the more specialised contributions reach a rare level: for example, L. W. Harrison on venereal disease, Macdonald Critchley on exposure after shipwreck, and A. A. Miles and R. E. O. Williams on airborne infections produce reviews of the first order, appraising the work of others from their extensive personal experience. At the same time, some balanced and informative chapters —e.g., on undulant fever, the serological typing of streptococci, and advances in hæmatology—seem out of place in this collection; for, though knowledge of these increased during the war, it did not increase as a result of the war. For an account of blood-transfusion we shall presumably have to wait for a later volume. A few authors give brief and tantalising notes on the medical experience of the enemy: these are of major interest and, because the information is hard to come by, might be extended in future volumes, or even be the subject of an additional volume.

It is a commonplace to say that in spite of the horrors of war we must be thankful for the benefits to medicine and science which derive from it. In this volume these seem less noteworthy than the mental attitude of almost every contributor. We entered war not only ignorant but recognising our ignorance and minded to learn; and every chapter records trial and error, patient observation, and determination to know the answer. A generation of doctors prepared to doubt and eager to seek is a great gain; and those who fear that the inquiring or statistical mind is linked with a heartless inhumanity will take pleasure in the kindly and personal sympathy with their patients which few of these Service doctors have been able to conceal.

Compared with the medical history of the previous great war, this book is better printed, better edited, less detailed, and less expansive; a better work for immediate reference, though possibly duller reading for the orderly officer on duty. The references are numerous, well chosen, and almost always accurately quoted.

Roentgen Manifestations of Pancreatic Disease

MAXWELL H. POPPEL, M.D., F.A.C.R., associate professor of clinical radiology, New York University. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1951. Pp. 366. 77*s.* 6*d.*

THE pancreas is a so-called silent area for the radiologist, because its density is equal to that of surrounding tissues and there is no contrast medium which is selectively secreted or concentrated by it. It is therefore all the more surprising to read a book of some 400 pages on the X-ray manifestations of pancreatic disease and to find that most of it is excellent and little redundant.

The stimulus to X-ray investigation has, of course, been provoked by advances in surgical technique which permit removal of large areas of the pancreas with a small mortality-rate, and survival without chronic invalidism. Pancreatic calculi are easy to diagnose by radiography and pancreatic cysts are readily localised by their characteristic impression on adjacent viscera; but much new information has been obtained by study of the radiological relation of the pancreas to the duodenum and bile-ducts and by correlating apparently trivial deformities with disturbances of function known or suspected to be associated with pancreatic disease. Deformities of the duodenal loop due to carcinoma of the head of the pancreas should be as well known to the radiologist as the niche of a gastric ulcer; and good lateral views enable him to diagnose large tumours of the body of the pancreas and differentiate them from other retroperitoneal masses. Disturbed motility of the small intestine, and stasis in the bile-ducts, are pointers to pancreatic disease, and should soon become as significant as pylorospasm with peptic ulceration. More spectacular is the association between pancreatic fibrosis and chronic pulmonary fibrosis, an observation first made radiologically by Neuhauser. The possibility of a relation between psoriasis and pancreatic dysfunction is, although speculative, a remarkable example of potential advances. Doubtless the more general use of aortography with direct visualisation of the pancreatic arteries will solve many obscure problems.

The author presents all these facets in a most detailed and yet modest way. This is a very intelligent book, admirably combining radiology with anatomy, physiology, and pathology. Its illustrations are excellent.

New Outlook on Mental Diseases

F. A. PICKWORTH, M.B., B.SC., consultant pathologist, Group 6 Hospitals, Birmingham. Bristol: John Wright & Sons. 1951. Pp. 304. 60*s.*

THE learning, integrity, and sustained effort that have gone into this book enforce much respect: Dr. Pickworth has devoted his life to the studies and views here so elaborately presented. He has had the courage to leave the highroad of contemporary thought about the pathology of mental disease and pursue his original and unaccepted ideas devotedly. Only a reviewer converted to his beliefs could say that the outcome justified Dr. Pickworth's constancy. His thesis is that chronic infections produce a pathological condition in the cerebral blood-vessels leading to interference with the labile patterns of blood-flow in the brain upon which normal behaviour depends: and so mental disorder occurs. This he illustrates with much ingenuity, even going so far as to account for thought, judgment, and other mental functions in terms of cerebral vascular architecture and direction of blood-flow. It is easier to discern in Dr. Pickworth's book a dominant theme than a counterpoint of self-criticism interwoven with the argument: this deficiency gives the work a strong flavour of *idée fixe*, reinforced by the loose and at times rather inconsequent exposition. The strictly histological section of the book is exempt from any such objection; it bespeaks Dr. Pickworth's notable contribution to the morphological study of the capillaries and smaller blood-vessels of the brain.

An Introduction to Abdominal Diagnosis

A Handbook for Students and Practitioners. ALAN E. LEE, M.D. Melb., F.R.C.S., F.R.A.C.S., senior visiting surgeon, Brisbane Hospital, Brisbane. Sydney: Australasian Medical Publishing Co. 1951. Pp. 176. 32*s.* 6*d.*

THE author of this book laments " the lack of any real interest in the mechanism of symptom production " and has attempted to study the nature of abdominal symptoms and to enunciate an acceptable theory by which they may be related to their various causes. This laudable ambition he has gone a good way to fulfil. His criticisms are, however, more applicable to chronic than to acute abdominal disorders.

The difficulty lies in choosing between several possible explanations of symptoms. Mr. Lee draws upon many sources and gives a fair account of the various theories of abdominal pain. Upon his personal and definite opinions, however, he bases an explanation of certain visceroptotic syndromes which may not find general acceptance. Theories are useful stimulants but not always faithful guides. Nevertheless we agree with him that clinical science should be cultivated.

The value of ancillary aids, such as radiography, is perhaps not sufficiently emphasised in this book; so long as a proper perspective be observed, such aids should be used whenever possible.

The Great Medical Bibliographers

JOHN F. FULTON, professor of the history of medicine, Yale Medical School. Philadelphia: Pennsylvania University Press. London: Oxford University Press. 1951. Pp. 107. 32*s*.

Dr. Fulton here publishes three lectures which he admits "did not afford adequate opportunity to deal with the contributions of the great medical bibliographers in any detail." Though one may regret that they were not expanded before publication, the three short chapters are packed with useful information and make an excellent starting-point for more detailed study.

The story begins with Johann Tritheim, a Benedictine bishop who had become an abbot in 1483 at the age of 21. The three most remarkable bibliographers were Conrad Gesner (1516–65), Albrecht von Haller (1708–77) and John Shaw Billings (1838–1913), and they were all remarkable men. Gesner's publications on bibliography were a mere tool to his larger aspirations, which included a comprehensive Greek lexicon, a huge volume on botany, and translations of surgical and medical texts. Haller was an infant prodigy who made good. At the age of 8 he had written 2000 brief biographies of historic persons and at 10 he had compiled a Greek lexicon with supplements in Hebrew and Chaldee. A practising physician, he found time to write long and detailed bibliographies in his own hand. He also wrote widely on many aspects of medicine, surgery, anatomy, and physiology. When he broke his right wrist he learned within 24 hours to write with his left hand. There was no limit to his accomplishment. Billings, the greatest of them all, conceived the vast Army Medical Library in Washington, and its unrivalled Index Catalogue, while he was still a student.

The text is adorned with a few portraits and reproductions of the title-pages of the most important works mentioned.

Roentgen Diagnostics

5th ed. H. R. SCHINZ, W. E. BAENSCH, E. FRIEDL, E. UEHLINGER. Translated by JAMES T. CASE, M.D., D.M.R.E. London: Heinemann Medical Books. 1951. Pp. 868. £12 12*s*.

BEFORE the war this German textbook of radiology, edited by Schinz, Baensch, and Friedl, was a standard European work frequently consulted by the English-speaking world. Though it was printed and published in Germany, its principal authors and editors were Swiss. It increased in size and scope as radiology progressed, and by 1939 had reached a fourth edition. During the war the standing type was destroyed by bombing, some of the contributors died, and the editors were faced with the enormous task of collecting new writers and new material. The result is an outstanding work, largely compiled by Swiss and Swedish radiologists, who—since both countries were neutral during the war—have had the leisure and incentive denied to the combatants. It is no longer a textbook but rather an encyclopædia of radiology.

This is the first of five volumes of the English version of the *Lehrbuch der Röntgendiagnostik*.[1] About a third of it deals with general principles of radiation physics and radiological interpretation, and the rest describes fractures and inflammatory and congenital diseases of bone. The illustrations are both fine and abundant, and the bibliography is vast. The four volumes yet to appear are on the same scale. The detailed text correlates radiological appearances with pathology superbly. Although Schinz stresses the clinical side of the picture, this is not quite so well done, nor is differential diagnosis given adequate consideration in some sections. Some rather unwary statements creep in, such as "the prognosis is bad in Paget's disease" or "sarcoidosis may first manifest itself as a renal calculus"; but these are vagaries of the individual author. The vast amount of scientific material, so well compiled and documented, makes this a reference work without equal in any language.

The English translation, by Dr. James T. Case, whose personal contributions to radiology in America have earned him international recognition, is completely literal, with many rather long and involved Germanic sentences. It would be possible to shorten the text greatly without loss of detail and accuracy; but he is to be congratulated none the less on the care with which he has undertaken so exacting a task.

The Extra Pharmacopœia (Martindale).—Volume I of the 23rd edition of this book, which was the subject of an annotation last week, is published by the Pharmaceutical Press, 17, Bloomsbury Square, London, W.C.1. There are 1352 pages and the price is 55*s*.

Tropical Medicine (6th ed. London: J. & A. Churchill. 1952. Pp. 560. 40*s*.).—The last edition of this work came out in war-time, and suffered the inconveniences attendant on that state of affairs. Now Sir Leonard Rogers, F.R.S., and Sir John Megaw, calling Sir George McRobert to their round table, have been able to include both the war-time discoveries and others made since, and so to present a thoroughly up-to-date account of their subject. Having in mind the needs of medical students, and of those many doctors who must treat tropical diseases without the help of modern laboratories, they have described carefully the methods of diagnosis which, as they say, can be practised "with the help of a microscope and a few simple appliances." With the same practical intention they give plenty of space to the common tropical diseases.

Textbook of General Surgery (6th ed. New York: Appleton-Century-Crofts Inc. 1952. Pp. 1154. £6.).—This well-esteemed textbook by Prof. Warren H. Cole and Prof. Robert Elman has been submitted to excisions, resections, anastomoses, grafts, and various plastic operations which have removed any traces of advancing age. It now carries new sections on chemotherapy and vascular surgery; and the sections on massive upper gastro-intestinal hæmorrhage, on preoperative and postoperative care, and on burns, have been rewritten. No attempt is made to give details of operations, though they are described in principle; non-operative techniques are fully explained. The teaching in this book has always been founded on physiology and surgical pathology, to the great profit, no doubt, of students who can afford to use it.

Problems of Ageing (Cowdry) (3rd ed. Baltimore: Williams & Wilkins Company. London: Baillière, Tindall, & Cox. 1952. Pp. 1061. 114*s*.).—This revision of Cowdry's text by Mr. A. I. Lansing, PH.D., comes at an opportune time, when the basic biological and pathological problems of old age are attracting much attention from biologists and clinicians. The editor's task has been thoroughly done. Most of the previous studies have been retained and expanded, and he contributes a new opening chapter on the general physiology of the ageing process, including a survey of his own work on the cumulative age-factor in rotifers. The chapter on qualitative histological and histochemical change has been brought up to date, though the sparsity of new observations is a measure of the amount still to be done. The important new observations in the chemical pathology of arteriosclerosis made by Gofman's team, using the ultracentrifuge, and by Siperstein studying the synthesis of cholesterol in the arterial wall, as well as the pathology of arteriosclerotic processes are reviewed. There is some overlapping here between the contributors, but no real redundancy. Other chapters deal with the production of experimental hypertension, the pathology of ageing in special systems and sense organs, and the physiology of homœostasis, with a certain amount on the surgery, demography, and applied social psychology of the age process. The most serious omission is the lack of a special section on the pathology of joint diseases (the word "arthritis" does not appear in the index) whose clinical importance in geriatrics is at least equal to that of the arterosclerotic group of diseases, less dramatic though their effects may be.

Dr. Lansing, who has himself contributed a great deal to the store of suggestive observation on this problem within a very short time, speaks in his preface of the depressing lack of new work on gerontobiology, and rightly congratulates the sociologists and psychologists on their more militant approach (though his sociological contributors might perhaps have shown more awareness of work done outside the United States). Silences in research often precede a storm of fruitful activity, and we may hope that this is the case with the biology of ageing.

THE LANCET

LONDON: SATURDAY, OCT. 4, 1952

Cancer of the Lung

THE vital statistics of the world show few trends iore dramatic than the rise during the last thirty ears in the notified death-rate from cancer of the ing; and there is little doubt that the increase is oth real and numerically important. Of the several recipitating causes suggested—exposure to tar, xhaust fumes from motors, industrial haze, and moking—the last strikes closest to the heart. We an accept quite philosophically risks from tarring f the roads and industrial pollution of the atmosphere hich are universal and at present unavoidable; and ew of us are asked to inhale carcinogenic hydro-arbons at work; but our control of our personal moking habits may decide our own fate. This sense f personal decision gives a piquancy to the various eports on the relation between smoking and cancer f the lung, of which the latest is the article on p. 651 y Dr. McConnell, Dr. Gordon, and Dr. Thelwall Jones.

Their investigation follows the same pattern as earlier studies by Muller,[1] Wynder and Graham,[2] and Doll and Bradford Hill [3] in which the smoking histories of patients known to be suffering from cancer of the lung are compared with histories given by control subjects, usually patients with some other disease. The Liverpool workers have also made collateral comparisons between the two groups with respect to other aspects of the life-history which might be relevant—namely, place of residence (past and present) and nature of occupation. In neither of these particulars did the lung-cancer patients differ from their controls. But before the possibility of occupational hazard is dismissed, it should be noted that this method of approach does not permit of any calculation of the number of people "exposed to risk" in particular occupations, and that only broad occupational groupings can be employed. As a result the presence of excessive death-rates from cancer of the lung among small occupational groups may be obscured. On the other hand, the information on smoking habits has been carefully collected from patients whose diagnosis is not in doubt, and, though the number of such patients is relatively small and the control subjects were interviewed two years later, the results bear comparison with previous work. Even with as many as 100 patients, chance variations in the proportion of non-smokers may be considerable, so that one looks for similar trends rather than complete agreement between the data reported from Liverpool and, say, the results of Doll and Hill. This is particularly apposite when one is tempted to seize hopefully on the suggestion that perhaps only the smoking of more than 20 cigarettes a day is really dangerous, because there is no technically significant difference between the proportions of non-smokers in the cancer and control groups. As the authors imply, this technically insignificant difference may well result simply from the smallness of the series observed. From Doll and Hill's data on 709 cancer patients and the same number of controls, there emerges a consistent upward trend in the apparent risk of developing cancer of the lung as the number of cigarettes smoked increases from 1 a day onwards, and until more data accumulate it would be safer to accept their gloomier view.

In each of the four studies mentioned, the approach has been the traditional clinical one of comparing the frequency of some personal habit among a group of patients suffering from a certain disease with "normal" expectation; and nowadays it has become customary to base that "normal" expectation on the results of identical inquiries from carefully paired control groups not suffering from the disease. To this approach there are, unfortunately, possible methodological objections. Patients with symptoms referable to the respiratory system may be more likely to exaggerate their smoking history. Again, in the study of coronary thrombosis, for example, the finding that patients with that disease more frequently gave a history of heavy smoking than did healthy men of the same age does not necessarily mean that smoking is a cause of coronary disease. Indeed, a critic with psychosomatic leanings might suggest that the cardiac lesion and the smoking excess were both expressions of some more deep-seated psychological disharmony: in other words, their observed association in the same patient was coincidental rather than causal. Strictly speaking, the proof that smoking causes cancer of the lung in men could come only from a deliberate experiment in which young subjects were allocated at random to groups given cigarette rations ranging from 0 to 50 per day and followed up until death. Such experiments, however, are possible only on animals, and only a modified form of a "forward" investigation is practicable. Whether one smokes or not is largely a matter of personal choice, and that choice may be bound up with other factors—social, occupational, and economic—which may be related to one's predisposition to cancer of the lung. Self-selection thus may introduce a bias in the "forward" just as in the "backward" clinical type of survey. Some at least of the possible sources of bias may be taken into account by restricting comparisons between different types of smoker and non-smokers to members of the same social and occupational group; and in one of two current "forward" studies that is being done. Readers will know of Professor Bradford Hill's appeal to the profession to record our smoking histories so that they may be filed for future reference. The implications may not have been immediately obvious, but the scheme has a stark simplicity. We classify ourselves on the basis of our present and previous smoking habits *now*—i.e., when we are likely to be unbiased by respiratory symptoms. *Later*, one of our colleagues will certify the cause of our death and we

---

1. Muller, F. H. *Z. Krebsforsch.* 1939, 49, 57.
2. Wynder, E. L., Graham, E. A. *J. Amer. med. Ass.* 1950, 143, 329.
3. Doll, R., Hill, A. B. *Brit. med. J.* 1950, ii, 739.

can then be added to the numerator of the death-rate whose denominator is the number of doctors of our age who share our smoking habits. In the fullness of time, a comparison between the lung-cancer death-rates in the various grades of smokers should give vital *evidence on the validity* of the present results of "historical" clinical studies.

A similar investigation is being made by the research staff of the American Cancer Society.[4] In view of the complications inevitable in trying to collect death certificates and other data from doctors in every State in the Union, the epidemiology panel of the society decided to exploit the enthusiasm for scientific and medical research which is the American's birthright. About 100,000 lay volunteers have been enlisted, and have been asked to complete a detailed questionary for not more than 10 of their friends over the age of fifty. Both present and past smoking habits are to be carefully recorded—the plutocrat who thinks in terms of x cigars per day, for example, is asked when he started, and how much and for how long he smoked the various forms of tobacco. At annual intervals thereafter, the lay worker is asked to report on the health of his "subjects," whether smokers or non-smokers. All eventualities have been foreseen. If (to use the phrase which is almost English in its under-statement) the research-worker is "not readily available," a substitute is nominated to carry on the yearly observation and report. It appears that non-smokers are commoner in the U.S.A. (roughly 10% of middle-aged men compared with our 5%). About half a million men are being observed, and it is estimated that, at current U.S. death-rates from cancer of the lung, four years must elapse before a comparison of the mortality experience of non-smokers and smokers of every degree will give a decisive answer to the question—is smoking conducive to cancer of the lung?

Both these "forward" studies have a wider interest from the methodological point of view, applying as they do essentially simple methods on a wide scale to the study of chronic disease. Their results will thus be awaited with quickened interest. Meanwhile, we can note some fresh evidence on the effect of atmosphere pollution on mortality from cancer of the lung. Some years ago Dr. PERCY STOCKS pointed out a broad association of rising cancer mortality with increased urbanisation,[5] and now, in an address to the National Smoke Abatement Society's annual conference, he has reported that the risk of dying from cancer of the lung in any area is closely related to the number of domestic chimneys (which are responsible for the large winter excess of arsenic and benzpyrene in the air), their concentration in the area, and the prevailing wind conditions. Large conurbations of more than 200,000 dwellings, like London, Manchester, and Merseyside, have lung-cancer death-ratios around 160, while Birmingham and Leeds ratios are 134 and 132 respectively, and Newcastle with its 87,000 houses has a ratio of 114. The effect of the prevailing wind has been highlighted by his showing that the black areas of high lung-cancer mortality in Finsbury, Shoreditch, Bethnal Green, Stepney, and Bermondsey coincide with the displacement by the wind of smoke from the congested heart of London. As STOCKS remarks, cancer may be defeated by the elimination of its precipitating factors rather than by any radical advance in treatment, and these studies should result in that precise identification which is the first step to removal.

Humidity and Infection

IN everyday life we are continually being reminded of the ways in which climate or weather may influence health and disease. The well-known difference between a "bracing" and a "relaxing" climate, the popular conviction that rheumatism is due to damp, and the evil consequences of sudden changes of *temperature—these examples are familiar.* Yet as a subject for serious investigation the effect of meteorological factors on body and mind is still generally neglected. Even the relation of weather to epidemics is not as well understood as one might suppose.

When he was studying smallpox in India, Sir LEONARD ROGERS [1, 2] showed that outbreaks which spread during dry weather came to a sudden end with the onset of the rains, and he established a correlation between low absolute humidity of the air and the incidence of the disease. In a paper which we publish this week Dr. B. B. WADDY reaches a similar conclusion about the behaviour of cerebrospinal fever in Africa. From their observations on previous epidemics he and others have suggested that this disease waxes when humidity is low and wanes when humidity rises; and the big epidemic on the Gold Coast in 1947–48 provided further evidence to the same effect. A fall in the average absolute humidity between November, 1947, and January, 1948, was associated with a steady increase in cases from 2 to 5 per week in November to the peak figure of 1711 in mid-March. On the other hand, a steady rise in absolute humidity, which started about mid-March and continued through April, was followed by a rapid decline in the number of cases during April and May. In fact the number of cases in any given week varied inversely with the absolute-humidity figures for the previous four weeks. From these facts about cerebrospinal fever, WADDY goes on to discuss two other respiratory infections in which there seems to be a similar relation to low absolute humidity—namely, lobar pneumonia [1, 2] and influenza.[3]

Recently SNOW [4] has investigated the connection between humidity and the incidence of poliomyelitis in Australia. The data here are somewhat confused: in some epidemics poliomyelitis behaved in the same way as the infections already mentioned, but in others the situation was reversed, the number of cases increasing as humidity rose. SNOW makes some interesting suggestions as to the ways in which humidity might influence the course of epidemics, and raises again the question of a direct effect on pathogenic micro-organisms. It may be recalled that EDWARD et al.[5] found that influenza virus suspended in the air survived much longer in a dry atmosphere

than in a humid one; and Loosli et al.[6] reported similar results. Likewise Williamson and Gotaas[7] and De Ome[8] found that several species of pathogenic bacteria lived longer in low humidities than in high ones. On the other hand some workers have found exactly the opposite. Dunklin and Puck[9] reported that a saline suspension of pneumococci, dispersed in air, survived well enough at low and high relative humidities, but at about 50% relative humidity the organisms died rapidly. Payne,[10] studying the survival of intestinal organisms on the hand, found that the time during which living *Bacterium coli* could be recovered from the skin depended on the relative humidity of the air: the organisms seemed to be killed most rapidly at humidities of 40–50%, but they surived much longer at higher and perhaps at lower humidities. There need be no surprise, however, at this conflict of evidence. It is clear that the survival of micro-organisms in an artificial suspension in air depends on a delicate balance between physical conditions—between, for example, humidity, temperature, state of dispersion, and the nature of the suspending fluid. At two extremes of temperature we know how critical such conditions can be. For the destruction of bacteria, saturated steam is far more efficient than hot air; while at low temperatures modern methods of freeze-drying have shown that bacteria can survive for years provided the freezing and drying are done in just the right way. The influence of humidity on the survival of pathogenic micro-organisms in natural conditions must be an even more complicated affair; for here we have to reckon with the influence of humidity not only on the organisms themselves but on the host and on the host's defences against infection.

A digression into physics and physiology is necessary at this point to make the distinction between absolute and relative humidity on which Waddy's argument largely hangs. Absolute humidity is measured by the actual *amount* of water vapour in the atmosphere: relative humidity expresses the amount of water vapour present under any given conditions as a percentage of the amount necessary to saturate the atmosphere under those conditions. The absolute amount of water vapour in the air on a hot dry summer day may actually be much greater than the amount on a cold wet winter day. For example, at 71°F. with a relative humidity of only 60%, the absolute humidity is about 11 g. per c.m.: but at 34°F even 100% saturated air contains only about 5 g. of water per c.m. Thus the low absolute humidity said to favour cerebrospinal fever might equally well be associated with hot dry weather in Africa and with cold wet weather in Britain. In endeavouring to explain the effect of this low absolute humidity, Waddy points out that when air enters the lungs it has reached or nearly reached body-temperature and is very nearly saturated with water vapour: the absolute humidity of saturated air at that temperature is 43 g. per c.m. This means that, except in very hot and damp weather, air in its passage from nose or mouth to lungs must abstract considerable quantities of water from the surfaces of the respiratory tract; and the drying of the mucosa may be much greater in winter than in summer. The complementary process is the familiar one by which expired air condenses rapidly on a cold day. It is evident that every breath may involve the transference of large quantities of water from one phase to another, and, as Snow remarks, this may considerably influence the activities of the respiratory mucosa. The effect may perhaps be beneficial, by stimulating a flow of fresh mucus, or it may be harmful, by causing either excessive secretion or excessive dehydration.

There are of course other ways in which changes in humidity could promote or inhibit the spread of infection. Many micro-organisms survive for long periods in dust, and dry conditions may well favour their spread by this means. Humidity could also act more indirectly—e.g., by an effect on sanitation or on the breeding of flies, mosquitoes, and other insects, or by causing people to congregate indoors. It is interesting, however, to note that, apart from poliomyelitis, the infections in which there seems to be the closest association with changes in humidity belong to what is usually regarded as the airborne type of infection—smallpox, lobar pneumonia, cerebrospinal fever, and influenza. Though the relation between humidity and infection is evidently complex, it is also important; and its very complexity should offer a challenge to epidemiologists, meteorologists, and statisticians. A great many relevant facts are doubtless available to anyone who is prepared to look for them in the right places, as Dr. Waddy has done.

A Pause for Thought

Not so long ago brooms were made with little exertion by gipsies and other dilettanti characters, and sold to the housewife at the back door. Since the invention of different and more scientific tools for cleaning houses, however, this primitive transaction has been overlaid; and nowadays no sooner has an inventor enunciated a principle than designers apply it, improvers improve it, and machine-makers make—first the tools to make the machines to make the invention, then the machines, and finally the parts of the invention itself. These are assembled by assemblers, loaded into trains and lorries by porters, sold by salesmen, and delivered by vanmen and their satellite boys. In fact, agreeable as labour-saving devices often are they seem to make a lot of work. Something of the same sort is happening in medicine. A new advance, though it may save lives and shorten illness, often entails such making of equipment, extension of buildings, enlarging of staff, training of teams, and general reorganisation as must cause the single-handed Victorian doctor to turn eagerly in his grave. Yet, it seems, not one of these things is done "properly"—that is, as precisely and exquisitely as its proponents advocate. Every branch of medicine could absorb more men and money, till imagination pictures the entire nation dedicated to the study of a single patient.

Social medicine faces some special problems, for our proper and reasonable concern for the welfare of the disabled, the deficient, and the old is being expressed in a great expansion of services. Mr. John

A. OLIVER, PH.D., speaking at Belfast on Sept. 8 at the conference of the British Association for the Advancement of Science, protested that we have *launched our vast social provision* (he was referring particularly to our provision for the elderly) in a philosophic vacuum. We hardly know what we are doing or why we are doing it, much less where it is leading us.

The fact that we have an ageing population is now well known. A sample taken from the 1951 Census returns from Great Britain indicates that already nearly 1 in 7 of the population are of pensionable age. The killing diseases of infancy, youth, and middle age have been so far mastered that more people now survive into old age. But they survive in a world where houses are scarce and domestic servants rare; few of them, moreover, have more than two or three grown-up sons and daughters to rely on in need, and many of them have none. Their grandchildren, too, have acquired a scarcity value, and get more room in the house, and more of their parents' attention, than children got in the past. The mother of a young family, determined to give her children the best chance she can, and also doing—perhaps in crowded quarters—all the family housework, cooking, washing, and mending, may not have much time, either figuratively or in fact, for an elderly relative. These things, Dr. OLIVER thinks, are combining to weaken the sense of family responsibility for old people; and the law is encouraging this decline: for though each of us is legally responsible for maintaining himself, though a husband and wife are responsible for maintaining one another, and parents are responsible for maintaining their children, there is now no legal obligation on any of us to look after our elderly relatives. The wide range of family responsibilities laid on us by the old poor-law have melted from the statute-book. To this new freedom Dr. OLIVER finds people react, broadly speaking, in one of two ways. Either they rejoice in the opportunity to push their elderly relatives into the care of the public authorities, or else they murmur reflectively that there is something wrong with the law, and that families ought to be made to look after their old people.

At all events, either as a cause or a result, the rise in public responsibility has been associated with a decline in private responsibility. The discovery of many old people, sick or dying in conditions of extreme neglect, has shown us the need for more hospital beds for the elderly, more long-stay annexes, and more residential homes. But, as Dr. OLIVER pertinently asks, how many more? Dr. J. H. SHELDON[1] in his study of old people in Wolverhampton, in 1947, found that 98% of them were living at home, either alone or with relatives: only 2% were in hostels or public institutions. Moreover, more than half the widowers or widows living alone had children living close at hand. This does not suggest any serious decline in family feeling. On the other hand, 7·7% of old people were causing "great strain" on the younger generation, the words being used to imply "a mode of existence which deprived the individual of a normal life and turned her into a drudge." It is often argued that these 7·7% should be having care elsewhere than at home; and, if the 2% already receiving institutional care are added this means that such care would have to be available for some 10% of the elderly population. That would mean, according to Dr. OLIVER'S estimate, some 20,000 homes or hostels in Great Britain, with 20,000 matrons, 20,000 cooks, and so on—in all some 100,000 people employed to look after 10% of the elderly. Such a state of affairs is certainly conceivable, he said, but is it economically possible, or socially desirable? That members of the younger generation under strain ought to be relieved goes without saying; but can we not relieve them in ways which are less disruptive of the lives of old people, less damaging to the sense of family responsibility, and less extravagant in the use of woman-power and money? Dr. OLIVER believes that we can—by providing home helps, sitters-in, sitters-up, laundering, chiropody, holiday schemes, and other medical and social aids "to ensure that the well-meaning daughter does not waste the best years of her life at the beck and call of some self-centred old tyrant"; and by providing more houses, perhaps with a suitable room or self-contained annexe, so that parents with young children can look after their old people and still keep something of the freedom they need to rear their families. Moreover we should help old people to go on working as long as they want to, and are able; for they have special attributes which younger people lack, and interest in work helps them to keep well and survive. The place for the old person, he said, like the place of anybody else, is in his own home; and we should help him to stay there as long as possible. It is certainly the place where most old people want to be.

It can be argued, of course, that by the time these extra services are provided the monetary saving would not be great; and that more women are needed to look after single old people in their own homes than would be required to look after the same number grouped in hostels. But Dr. OLIVER was concerned only secondarily with the financial aspect. His chief point was that the progress made in social work and legislation in the last ten years had been "achieved without any real preparation in fundamental thinking." If it becomes the fashion to put old people into homes and hostels something harmful will have befallen us all. "In the last analysis the values are nearly always moral values, and moral values are what gives purpose to politics."

A New Blood-donor Service

THE Ministry of Health announces the formation of a panel of nearly 2000 blood donors whose red cells have been completely classified and who will be available to give blood for transfusions in which the subdivisions of the blood-groups must be taken into account. Several hundred distinct combinations of blood-groups are covered by the donors on the panel, which is the first of its kind in the world. The preliminary testing and selection of donors was made by the regional transfusion centres, and the Blood Group Reference Laboratory of the Medical Research Council then carried out the detailed testing and classification. When a patient requires blood precisely compatible with his own, it will now be possible to ask a regional transfusion centre to select a suitable donor from the panel, and the search, which is often urgent, will be much simplified.

Annotations

THE MALNOURISHED MIND

STARVE a child of fats and sunlight and you create crippled dwarf. It seems feasible that a mind nourished n an unbalanced diet, and in a half light, may show omparable deformities. In his presidential address to he American Surgical Association this year, Dr. Daniel C. Elkin,[1] putting the case for the study of the humanities in the making of a doctor, asserted that we have emphasised the science courses for "premedical" tudents to the detriment of their education. He was peaking, of course, of America, but his arguments apply here aptly enough. He had been struck by the gnorance and the actual illiteracy of many doctors; and by the narrow and utilitarian outlook of students applying for places in medical schools. If these young people, most of whom have "taken science" in their last two years at school, are asked "why did you take these subjects," they often reply that they have been told by their advisers that this is the surest way to get into a medical school. He quoted Sir Richard Livingstone's opinion:

> "It is characteristic of today that, when we discuss which subjects should be studied, or which languages should be learnt, the first consideration is nearly always utility; we ask what is most useful for the machine, not what is most likely to make a good human being."

Some enlightened medical schools urge prospective students to acquire a liberal education, and declare that admissions committees will not be impressed by a history of two years of school science. But in actual fact, the candidate follows such advice at his peril[2]; for coming freshly to science in competition with those already grounded in it he is liable to flounder through his first year, fail in his 1st M.B., and so (in this country, at any rate) risk his place in the school, and with it his only chance of training as a doctor—a curious punishment for attempting to broaden his mind.

The question is not merely of literacy, or of acquiring the ability to carry on an educated conversation. It goes far deeper, Dr. Elkin believes; for beyond the content of the curriculum there are the values. The worth of a humane education—by which he clearly means education in history and letters rather than in dead languages—is to give the learner, he says, "a perception of the rôle of mankind as revealed in its history, its wisdom, its beauty; its ugliness, its growth, its regressions—in brief, its life." It is "a catalyst in the perception of the truth that 'shall make ye free.'" It would be wrong, of course, to suppose that this is the prerogative of the humanities alone. An understanding of the theory of evolution is also a catalyst in the perception of truth; and medical students are not the only young people nurtured on an unbalanced diet: the science-starved arts student can be as mentally rachitic as the scientific philistine. Dr. Elkin, however, was also concerned to remind us that the student who has learned science and nothing else is particularly vulnerable to the devices of unscrupulous seekers after power. The receptiveness of the mind depends much on the transformer, emotion; and while we have been ignoring this fundamental fact "the barbarians" have been learning to use it.

> ". . . the modern barbarians," he quotes Stanley Dorst as saying, "do not destroy science and technology, they do not wipe out the machine values, but convert them into terrible forces of evil and death so that those who would out-do their mad rush must out-do them in ruthlessness. What they do destroy with devastating thoroughness is liberal culture of the people. They destroy their roots in the past, their libraries, their free press, their religion, their belief in the essential dignity of man. In short —destroy the education which makes men free."

Facts, figures, techniques will change many times in a student's lifetime; values last; and the responsibility of teachers (in medicine, as in other subjects) is to teach the young to distinguish values—to demonstrate, as Dr. Elkin says, that there are other things than technique in surgery, science in medicine, and knowledge in life. "We have expected too much of science, and in so doing we have been trimming down those lamps of education which shed our best light."

ABDOMINAL AORTOGRAPHY

THE progress in angiocardiography and cerebral angiography that has followed the introduction of new contrast media and apparatus has reawakened interest in translumbar aortography as a means of investigating abdominal disease. Its usefulness has already been established in certain renal conditions and in lesions of the abdominal aorta and its branches.

The pioneer work was done by Dos Santos as early as 1929.[1] The technique is relatively simple: with the patient prone, a 16 or 17 B.W.G. needle is inserted below the 12th rib, a hand's breadth to the left of the spine; it is then directed forwards, medially, and upwards, using the vertebral body as a guide, until it enters the aorta. In order to display the kidneys and the splenic and superior mesenteric vessels the needle must be at the level of D12: at the level of L2 only the inferior mesenteric artery and aortic bifurcation will be shown. 20 ml. of 70% diodone is injected rapidly either by hand or by some form of pressure apparatus. To get the best results from the examination, serial films should be taken during the next 10 seconds.[2] A more elaborate method described by Farinas[3] involves retrograde catheterisation via the femoral artery. The aorta and the renal and splenic vessels are seen most clearly in the first 2 seconds, while the density of the renal shadows increases for about 5 seconds. When a larger quantity of diodone (30 ml.) is used the portal vein may be seen in 7–10 seconds.[2] The abdominal aorta and the renal, splenic, and superior mesenteric vessels are clearly seen, and in most cases a well-defined outline of the cortex and medulla of the kidney is obtained. The spleen and wall of the gut also increase in density as the diodone accumulates in them.

Aortography can often decide, before operation, the nature of filling defects visible on intravenous or retrograde pyelograms. For instance, a cyst shows as a clear avascular area; and an abnormal circulation may be demonstrated when a neoplasm is present. Well-defined patterns are being recognised in polycystic disease and hydronephrosis.[4 5] Again, information may be gained about the origin and distribution of the renal arterial supply, and may help the surgeon in planning a local resection of a kidney. The size of the renal arteries and the depth and density of the cortex may give some assessment of renal function or indicate the degree of damage in a diseased kidney. In occlusive disease of the aorta and iliac arteries, the site and extent of the process can be determined and the anastomotic circulation outlined. Aortography has been little used in disease of the pelvic viscera, and it has so far been disappointing in demonstrating hyperplasia or tumour of the adrenal gland. However, Weyde[5] has noted changes of possible significance in two cases of early renal tuberculosis.

3. Farinas, P. L. *Amer. J. Roentgenol.* 1941, 46, 641.
4. Weyde, R. *J. Oslo City Hosp.* 1952, 2, 3.
5. Weyde, R. *Brit. J. Radiol.* 1952, 25, 353.

The procedure seems to carry little risk; for there has been no fatality in the 3500 published cases, though thrombosis of the superior mesenteric artery has followed accidental direct injection. Local anæsthesia is usually adequate, but a small dose of thiopentone can be given to apprehensive patients. The injection of diodone is usually followed by a feeling of warmth. Accidental injection into the paravertebral tissues may cause intense local pain, but nothing worse, and the diodone is rapidly absorbed. The investigation should not be performed in patients with severe hepatic or cardiac disease or with nephritis. At present it seems likely that abdominal aortography will, because of its cost and complexity compared with other forms of investigation, be reserved for those cases of renal disease in which simpler investigations have failed to give a definite answer, but it may well prove of increasing value to the surgeon in his treatment of occlusive disease of the aortic and iliac arteries. Further research may extend its use to other viscera and show whether it can be applied to lesions of the portal system.

RUBBER HAZARDS FOR THE SKIN

DERMATITIS is well known as a hazard in the rubber industry; and in the U.S.A. it apparently involves some 3% of workers.[1] In addition, those who use rubber appliances of any sort are liable to be affected. Rubber is now used so extensively that dermatitis from this source may not be recognised unless the possibility is borne in mind. Thus, trouble may arise from such commonplace causes as rubber fittings on clothing, rubber gloves or sponges, or the more unusual eyelash curlers or "gay deceivers." Leider et al.[2] have analysed 125 cases of proven rubber sensitisation. Rubber sponges were the cause in 40, rubber gloves in 17, and rubber parts of garments in 25. Other causes mentioned by these and other workers include dress shields, condoms, rubber bands, kneeling-pads, finger-guards, bathing-caps, dental dams, goggles, bunion protectors, earphones, and stethoscope fittings. Eczematous sensitisation to adhesive dressings is sometimes due to rubber[3] and not to some component of the "spread."

Crude rubber is vulcanised with the aim of increasing its strength, elasticity, and resistance to temperature changes. With crude rubber sulphur is used; but purified rubber needs the addition of accelerators, which also reduce the amount of sulphur required. Modern accelerators are mostly organic compounds, such as hexamethylene-tetramine (a potent skin irritant), carbon disulphide, aliphatic amine addition products, substituted guanidines, and mercaptobenzothiazole. Many accelerators are rendered yet more effective by activators, such as metallic oxides and fatty acids. Finally there are anti-oxidants, age-resisters, or stabilisers, which retard the atmospheric oxidation that otherwise proceeds rapidly in raw or even vulcanised rubber.

Mallette and von Haam[4] have studied the skin-irritating and skin-sensitising properties of twelve compounds widely used in the industry. Skin tests showed that the compounds of all three groups—accelerators, activators, and anti-oxidants—were mild to severe irritants and that many, especially in the anti-oxidant group, were moderately sensitising. It is no easy matter to determine the exact cause of eruptions due to rubber, owing to its many varieties and the reticence of some manufacturers and firms using rubber materials. In a case of pruritus vulvæ from sensitisation to a condom Clarke[5] traced the cause to free alkali from potassium oleate used as a stabiliser. That sensitisation may arise from substances present in very small amounts is suggested by Bettley,[6] who has described the case of a patient who was sensitive to rubber containing benzthiazole. Solutions of this substance gave positive patch tests when diluted to 1 part in 10^{14}. This patient even reacted to indirect contacts—blankets on which rubber hot-water bottles had lain—and this was verified by patch tests with lint which had lain loose in a match-box with a piece of rubber for three days. According to Ellis and Siegel,[7] the accelerators in some rubbers are loosely incorporated and are "leeched" out by sweat, or if in excess they may "bloom" out spontaneously. Irritating or sensitising compounds may also be continually formed on the surface of certain "vapour-cured" rubbers. Blank and Miller[8] have found that the commonest cause of an allergic, eczematous, contact-type dermatitis of the feet is the anti-oxidant monobenzyl ether of hydroquinone, which is used in the rubber adhesive in the combined linings of shoes.

In addition to dermatitis, leucoderma may occur from exposure to rubber dust; here again the cause is the monobenzyl ether of hydroquinone, which presumably interferes with the oxidation of tyrosine to melanin. Zakon and Goldberg[9] noted 9 examples amongst 200 workers all similarly exposed, and concluded that other factors besides contact are needed to produce this disorder, one being an alkaline skin reaction and another the solution by sweat of anti-oxidant from rubber. Leucoderma may also arise among the users of rubber articles; Leider et al. have described leucoderma of the penis from the use of condoms, and leucoderma round the mouth from rubber sheeting used as a dental dam.

THE LOCK

AFTER 206 years as a centre for the treatment of venereal disease, the London Lock Hospital is to close on Oct. 31. Thus ends a famous descendant of the lazar-houses of the Middle Ages, which were diverted from the care of leprosy to that of syphilis when the latter disease swept Europe at the end of the 15th century.

William Bromfeild, surgeon to St. George's, founded the Lock in 1746 in Chapel Street, a stone's throw from his own hospital, because there was no other place for the treatment of venereal disease in the rapidly extending West End of London. For the first hundred years it was staffed largely by George's men. John Hunter walked its wards as a student, but he quarrelled so much with Bromfeild, Hawkins, and Gunning that he never got on the staff. Samuel Lane and Edward Cutler were both surgeons to the Lock, and each applied for appointment to the staff of St. George's. Lane was the proprietor of a successful private school of anatomy, the Grosvenor, where the George's students did their preliminary work, and it was thought he was sure of the post; but Cutler won. The disappointed Lane moved his school to Paddington and with his friend, William Coulson, there founded St. Mary's Hospital and its medical school. In the next hundred years three generations of Lanes served St. Mary's and the Lock—Samuel, James, and Ernest. Walter Coulson was also one of its surgeons, but there seems to have been some trouble there, for with his uncle William he founded a new hospital in Berners Street, which he called St. Peter's Hospital for Stone. Thus the Lock Hospital

as responsible to some extent for the foundation of oth St. Peter's and St. Mary's.

Many distinguished men served the Lock, including eate (an early master of the College of Surgeons), Villiam Blair (the friend of Lettsom, whose portrait ppears in Medley's picture of the founders of the Iedical Society of London), Berkeley Hill, Alfred Cooper nd Jonathan Hutchinson the younger. Addison was ts most distinguished house-surgeon, and David Living-stone was probably its most famous postgraduate.

The records of the hospital from 1746 to 1952 are omplete, and they cover, as nothing else could, the istory of the treatment of venereal disease in England luring that time. On no account must they be lost, nd we hope they will be placed in the safe keeping of, say, one of the Royal Colleges, the Royal Society of Medicine, or the Medical Society of London.

VISCERAL ANALGESIA IN TABES

IT has been known for some time that tabes dorsalis may on rare occasions account for loss of painful visceral sensations and so mask abdominal catastrophes, though few examples have been published. Recently Grimble and Csonka[1] have described the case of a tabetic of 59 who seemingly died of heart-failure although at necropsy they found a large chronic gastric ulcer which had apparently perforated some three days previously. The abdomen had been distended and tympanitic during his last days, but he had no tenderness or pain and had been able to eat solid food an hour before he died. The pathological findings in the central nervous system were those of moderately severe tabes with posterior-column degeneration, conspicuous leptomeningeal thickening extending out to invest the posterior nerve-roots (which showed small areas of scarring), and moderate marginal demyelination of the entire cord. There were no local lesions in the brainstem.

In discussing their patient, Grimble and Csonka recall that Bockus[2] described three visceral pain mechanisms: (1) true visceral pain, which is produced for example by stretching the capsule of a solid organ, or by distension of a hollow viscus, and which is transmitted by afferent fibres along sympathetic pathways; (2) referred pain, the exact nature of which is still not understood; and (3) pain which Morley[3] has called the "peritoneo-cutaneous reflex," which has been transmitted from peritoneal nerve-endings via afferent somatic fibres, and which is felt in the corresponding segmental skin area over the abdomen, where it may be associated with muscular rigidity. They believe that in their patient not only were visceral pain impulses from the stomach via the splanchnic nerves interrupted, but other routes traversing somatic nerve-fibres were probably involved as well; for he had shown extensive hypalgesia over the whole trunk, and the peritonitis following perforation had been completely silent. They also infer that bladder afferents had also been interrupted because for some time he had had an insensitive bladder which often became distended without discomfort.

The subsequent course within the spinal cord of visceral pathways in man is to some extent still in dispute. Hyndman and Wolkin[4] concluded from their experience with anterior chordotomies that the spinothalamic tracts carried visceral pain sensation from every source: in this they disagreed with White[5] who stated that interruption of the spinothalamic tracts would not relieve the sensation of a distended colon or bladder. More recently, however, McMichael[6] reported the pathological findings in a patient with Erb's syphilitic spinal paralysis who had lost sensation of bladder fullness, and he concluded that the cord pathways for bladder afferents in man lay in the posterior and superficial regions of the lateral columns, where Barrington[7] had shown them to lie in cats. Strong support for this view was provided last year by Nathan and Marion Smith[8] from a detailed study based on 27 patients who had been subjected to unilateral or bilateral anterolateral chordotomies; they showed that the pathways subserving sensations of bladder fullness, as well as pain of urethral and ureteric origin, lie within the spinothalamic tract on the surface of the cord opposite the dorsal lateral process of the anterior horn of grey matter. It seems possible, therefore, that in Grimble and Csonka's case afferent fibres from the bladder were disrupted within the cord as indicated by the marginal demyelination found at necropsy. As they admit, their case has not added to our knowledge of the neuro-anatomy of visceral pain pathways, but their report is of value in that it draws attention to this interesting and potentially dangerous complication of tabes dorsalis.

A NEW MURMUR

MURMURS in the cardiovascular system are produced by turbulence in the blood-flow from narrowing or other irregularity in the blood passages. Vibrations are set up in the vessel walls, and the resulting sounds are conducted particularly well in the direction of the blood-flow.

A new physical sign of compression of the subclavian artery at the thoracic inlet has now been described by Edwards and Levine,[9] who find that a bruit is audible over the affected artery in the posterior cervical triangle. Sometimes this is heard with the patient in the resting position; but it is intensified—and may only be heard—when he tenses the scaleni by depressing the shoulder and bending the neck away from the affected side.[10] With this manœuvre Edwards and Levine find it easier to detect different degrees of the murmur than the accompanying variation in pulse-pressure. (This accords with general experience in feeling the pulse while listening to the diastolic range of sounds.) A microphone can be substituted for the stethoscope, and a permanent visual record obtained from a recording electrocardiograph, the other channels of which can be used for synchronising the tracings with those from heart leads.

Vascular symptoms in patients with cervical rib or scalenus syndrome seem usually to be due to compression of the subclavian artery, either by an aponeurotic band from a scalenus muscle or by the rib itself; but sometimes clavicular pressure may play a part. This was clearly shown by Eden.[11] In treatment scalenotomy has given place to formal dissection of the vasculonervous bundle in the affected region. Direct pinching of the subclavian artery is a more familiar feature than it was when Lewis and Pickering[12] described it in Trotter's patient with Raynaud's syndrome and a cervical rib. Diagnosis, however, is not always easy. The majority of patients have no cervical rib; and pain in the arm and Raynaud's phenomenon are often ascribed to causes other than compression of the bundle at the limb root. The simple auscultatory test described by Edwards and Levine may prove most useful in detecting such compression and in indicating the cases that require operation.

CLIMATE AND RESPIRATORY INFECTIONS

B. B. WADDY
B.M. Oxfd, D.P.H.
SPECIALIST (EPIDEMIOLOGY), COLONIAL MEDICAL SERVICE, GOLD COAST

INFECTIONS acquired via the respiratory tract occur in epidemic form during the dry season in tropical Africa, and major epidemics, particularly of cerebrospinal *meningitis* (C.S.M.), *are confined to arid regions.* In temperate climates respiratory infections are at their height in late winter and spring. This contrast seems to have been accepted without explanation. Banks (1942), writing on C.S.M., said:

> "A fall in temperature or else a rise in humidity appear to start the upward trend of the disease, the maximal effect being apparent a month or so later. Exceptionally, as in the Sudan, the change to dry dusty weather is associated with the disease."

Experience, especially of C.S.M., in the Northern Territories of the Gold Coast has led me to speculate on this apparent discrepancy, and I propose to put forward evidence that the common factor is low absolute humidity (A.H.).* That low A.H. is an important factor in the epidemiology of lobar pneumonia and smallpox in a tropical climate has already been stated by Rogers (1925, 1926), but its significance appears to have escaped attention. In a temperate climate, such as that of England, A.H. is lowest in the winter and highest in the summer.

Many of the figures I shall use in this paper are not superlatively accurate, but they are accurate enough to serve as illustrations and no further apology will be made for them.

RESPIRATORY INFECTIONS IN TROPICAL AFRICA

In the countries bordering on the Sahara, lobar pneumonia becomes epidemic, to an unknown extent, every dry season, and smallpox epidemics, when they occur, do so during the dry season and fade out when rain begins to fall. The spectacular epidemics of C.S.M. in the Sudan, Nigeria, and the Gold Coast between 1930 and 1950 have received more attention than the other diseases. The rise and fall of C.S.M. in relation to the climate are much more clear cut than those of smallpox, and the epidemiology of smallpox is obscured by vaccination campaigns. I suspect that lobar pneumonia has a sharply defined epidemic season, but few figures have been collected. C.S.M., therefore, is the only example of tropical epidemiology that I shall discuss in any detail.

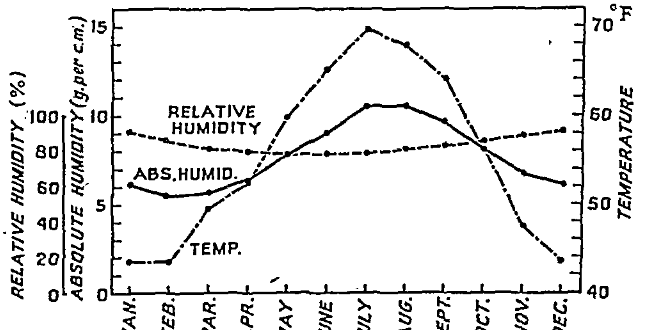

Fig. 1—Average temperature, relative humidity, and absolute humidity at Kew observatory.

C.S.M. is a disease of the dry season in dry places; epidemics are cut short with dramatic suddenness by wet weather and places with humid climates are free from serious epidemics. Usually an epidemic ends with the fall of rain, but there are records—e.g., in the Sudan—of an epidemic fading though no rain fell. Epidemics work round in cycles from the Sudan to Nigeria, on to the Gold Coast and back through the French territories to the Sudan.

The Lobi country in the western part of the Northern Territories of the Gold Coast suffered terribly in the early years of this century (Walton Claridge 1915) and again in the early 1920s. The Gold Coast became reinfected with a small outbreak in the north-east in 1939. The western side of the Northern Territories was again attacked in 1942, and in 1945 there was an epidemic of 9864 cases in a population of about 250,000 (Browne et al. 1947). In this area conditions of close crowding and bad ventilation could hardly be worse. The houses have no windows and only a small hole for a door. The occupants often sleep huddled close together for warmth.

Temperature and humidity were measured at 6 A.M. There is negligible correlation between the number of cases and A.H. for the same week, but if the disease [illegible] with A.H. of the previous four weeks, th[illegible] is −0·33 (standard error 0·20) which is [illegible]

The figures of seasonal C.S.M. in the Sudan, Nigeria, and the Gold Coast indicate a degree of mass immunity following a major outbreak. In the western Northern Territories there were 853 cases in 1944; 9864 in 1945; and 52 in 1946. In Nigeria the number of cases reported in some of the big epidemics were only guesses, but the figures show the same fall after an outbreak. In the Sudan the disease did in fact die out in the area affected by the big epidemic of 1936 (Elliott 1947).

This trend—the building up from season to season until a really big epidemic occurs and then the sudden drop—is, I think, a fair indication that the carriers must greatly outnumber the cases, and that carrying the infection does confer some degree of immunity.

ATMOSPHERIC HUMIDITY AND C.S.M. IN THE TROPICS

It has been assumed that rain stops an epidemic by reducing dust-transmission; indeed, watercarts have been used in town streets in an effort to do this.

At the beginning of the dry season night temperatures are lower than at any other time of year. The population ongregates more closely at night, and this has been dvanced as the main cause of the seasonal variation of .S.M. But during the rains nights are quite cold enough o cause exactly the same crowded sleeping conditions; have studied the sleeping habits of people in the western Northern Territories and they are if anything worse in the rainy season when leaking rooms are abandoned and dry ones take an extra quota of humanity. Nevertheless, only sporadic cases of C.S.M. occur at this time.

---

* Absolute humidity is measured by the actual amount of water vapour in the atmosphere (in grains per cubic foot or grammes per cubic metre).

The relation of C.S.M. to relative humidity (R.H.) † in tropical Africa has been discussed before.

Riding and Corkill (1932) showed that the incidence in Khartoum rose as humidity fell and vice versa. The association was graphically exact and rain was assumed to be the cause. Corkill (1939) convincingly discounts actual rain as the factor. He writes: "In the epidemic . . . the association was clear and constant," but he adds that subsequent epidemics have sometimes declined before R.H. started to rise, and he discarded the theory that variations in R.H. were the immediate cause.

White (1942) reported an epidemic in Tanganyika which began to decline when R.H. was still low. He commented on the outbreak of sore throats which always accompanies an epidemic, and remarked that it was probably caused by drying of the nasopharyngeal mucosa. The decline of this epidemic may be wholly or partly explained by its long duration and the relatively small number of cases (about 900). Steps to avoid overcrowding were taken and should have had some effect after the epidemic had reached its peak.

The Gold Coast epidemic of 1945 ended when patchy showers fell in only parts of the district; an association with low R.H. suggested itself to me at the time, but the only figures available are too inaccurate to reproduce. All that can be said is that the epidemic coincided with a typical dry season, the curve of humidity in the Northern Territories showing a rapid drop in December and a slower but steady rise towards the end of February. Unexpected showers make very little difference; the climate is dependent on wind from the Sahara.

The next major epidemic of C.S.M. was in the Northern Territories in 1947–48, and here I was able to obtain accurate figures of temperature and humidity. The figures were recorded at Tamale, more or less in the centre of the Northern Territories, where the climate is typical of the whole, though in the extreme north the dry period lasts slightly longer and is a little more severe.

Table I shows the weekly figures and the corresponding number of cases of C.S.M.

TABLE III—OUTDOOR AND INDOOR HUMIDITIES, ENGLAND, 1947—SPECIAL CASES

Conditions		Outdoors				Indoors			
		Dry bulb (°F)	Wet bulb (°F)	Relative humidity (%)	Absolute humidity (g. per c.m.)	Dry bulb (°F)	Wet bulb (°F)	Relative humidity (%)	Absolute humidity (g. per c.m.)

Underground bakehouse; baking not in progress		42·5	35·5	47	3·67	57·0	48	50	5·96

* Figures from Angus and Luxton (1947).

Overcrowding and badly ventilated sleeping accommodation have recently been somewhat discredited as causes of the spread of C.S.M. However, during the epidemic cycle in the Northern Territories, from 1945 to 1950, there was no confirmed case of C.S.M. in a European, only one case among hundreds of African nurses, and only one among the servants of Europeans—a young boy who slept in the town and not in the servants' quarters at his employer's house.

RESPIRATORY INFECTIONS IN TEMPERATE CLIMATES

A graph of the annual variations of temperature, absolute humidity, and relative humidity in England (measured at 1 P.M. at Kew observatory) shows that A.H. is at its lowest during the winter and highest in July and August, and that A.H. in a temperate climate bears a much closer relation to the temperature than to R.H. (fig. 1).

---

† Relative humidity is expressed as the percentage of water vapour in the atmosphere as compared with the amount necessary to saturate it under the existing conditions.

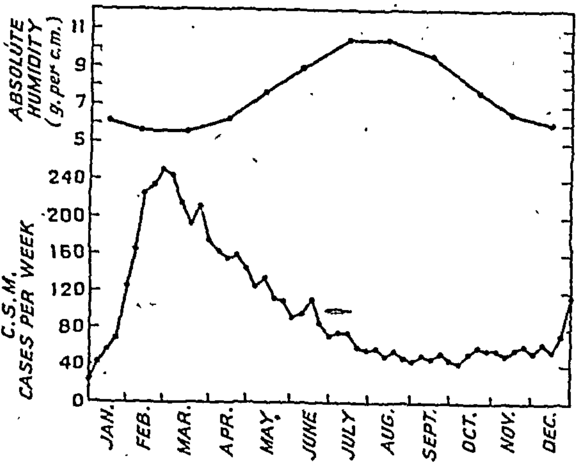

Fig. 2—Cerebrospinal meningitis in England and Wales (1940) related to average seasonal absolute humidity.

Most respiratory infections are probably acquired indoors in the ways delightfully recorded by Pickles (1939). I could not find any figures which compared the outdoor and indoor atmospheric conditions in England, and I therefore recorded some myself during the winter of 1946–47 (table II).

In a room without double glazing A.H. does not rise very much above that out of doors, and it is certainly not as high as the average summer A.H. The reason for this is fairly obvious; any excess water vapour promptly condenses on the windows and walls which are cooled from outside.

Mr. T. C. Angus, D.SC., of the London School of Hygiene, very kindly gave me figures recorded in a badly ventilated Army hut under conditions similar to those studied by Glover (1918). These figures and some further observations of my own are given in table III.

Changes in outdoor A.H. follow those indoors sufficiently closely to be used in studying the relation of A.H. to respiratory infections.

I have not studied the daily weather readings for the year 1940, but a graph of the C.S.M. epidemic of that year and of the average seasonal A.H. shows a fairly clear association (fig. 2).

I could find only one long series of observations on the carrier-rate of C.S.M. in England (Glover 1918). These figures were not taken regularly every week, and the 4-weekly averages which I have taken from Glover's graph are probably not exact. Table IV shows these averages and the corresponding Kew figures for temperature and humidity.

The coefficient of correlation for the carrier-rate and A.H. of the same 4-weekly periods is —0·65. That for carrier-rate and A.H. for the previous 4-weekly period is —0·73. The standard error is 0·29, so both the figures are significant. R.H. has no association with the carrier-rate.

TABLE IV—TEMPERATURE, RELATIVE AND ABSOLUTE HUMIDITY, AND MENINGOCOCCAL CARRIERS, SEPTEMBER, 1917, TO SEPTEMBER, 1918

(Glover (1918) defined the organisms as "gram-negative cocci morphologically indistinguishable from meningococci")

4-weekly period	Temperature (°F)	Average relative humidity (%)	Average absolute humidity (g. per c.m.)	Carriers (% of persons examined)
1	61·5	76·5	10·3	—
2	55·5	84·0	9·4	21
3	45·0	85·5	6·5	39
4	44·7	85·0	6·4	41
5	34·8	81·0	5·8	57
6	41·7	84·0	5·3	81
7	43·3	86·0	6·4	67
8	41·2	80·5	5·5	40
9	44·0	82·0	6·2	29
10	52·5	74·0	7·8	67
11	59·5	64·5	8·5	49
12	60·5	68·0	8·5	26
13	63·4	75·5	11·2	23
14	61·0	74·0	10·3	13

Glover associated overcrowded sleeping conditions with a high carrier-rate, as did Peters and Gunn (1929) and Whittingham et al. (1931). But the Medical Research Council (1918) cast some doubt on the relation of C.S.M. and bad ventilation per se.

I believe that the relation of carrier-rate, disease, and climate could be studied conclusively in countries close to the Sahara, if the necessary laboratory equipment were available.

INFLUENZA

The pandemic of influenza had three waves, two in 1918 and one in 1919.

The Ministry of Health (1920) quoted the report of the French Direction d'Hygiéne, which observed that the mortality in 1918 was low during a remarkably dry and cold spell in France from May to June. It then went up slowly, and came down again when the weather became warmer and unusually heavy rain fell. It rose again towards the end of a dry August. September and October had 6 weeks of drought with temperatures below normal; this was a peak period for deaths from influenza. In November temperatures became normal again and abundant rain fell; the death-rate decreased. Another cold spell followed and a second mortality peak occurred.

TABLE V—INFLUENZA, TEMPERATURE, AND ABSOLUTE HUMIDITY, LONDON, 1918 TO 1919

Week of year (1918)	Temperature (°F)	Absolute humidity (g. per c.m.)	Influenza deaths	Week of year (1918)	Temperature (°F)	Absolute humidity (g. per c.m.)	Influenza deaths

Low A.H. is an adequate measure of coldness and dryness, so recourse has again been made to contemporary weather readings. At the time of the pandemic waves, A.H. was lower than average. Table V gives the climate figures for London only, but the Ministry of Health (1920) state that the London weather was typical of that for the whole British Isles.

The three waves of influenza began respectively in the fifth, fifth, and seventh weeks after a pronounced decline in A.H. The waves passed their peaks and declined five, six, and three weeks after A.H. began to rise again. The Ministry of Health report says:

> "These results suffice to establish a *prima facie* case in favour of the view that an unseasonable deviation of weather towards the side of coldness played some part in the mortality of the epidemics. They not less clearly testify against any claim that weather conditions rank among the primary factors of epidemic prevalences."

There could be no fairer summing-up. None the less the connection does exist.

LOBAR PNEUMONIA

The report also analyses the weekly incidence of lobar neumonia in relation to the temperature of the previous reek for the years 1850–89 and 1903–14. The coefficients f correlation are as follows :

First quarter, 1850–89	.. ..	−0·371
Fourth ,, ,,	.. ..	−0·686
,, ,, 1903–14	.. ..	−0·707

(The standard errors are 0·046, 0·046, and 0·087.)

In view of the connection I have indicated between he temperature and A.H. in temperate climates, and etween lobar pneumonia and the dry season in tropical Africa, the statement of Rogers (1925, 1926) that lobar pneumonia and low A.H. are closely correlated is confirmed.

CRITICAL ABSOLUTE HUMIDITY

Rogers gives a critical figure of 0·7 in. Hg (the equivalent of 17·2 g. per c.m.) as a critical figure for A.H., above which smallpox dies out. This figure is seldom if ever reached in England, but it may correspond to a critical figure for the Northern Territories of the Gold Coast.

If there is a critical value for C.S.M. the English and Gold Coast figures suggest that it may be in the region of 10 g. per c.m.

AIRBORNE ORGANISMS AND ABSOLUTE HUMIDITY

Robertson (1943) mentions high humidity as being rapidly fatal to organisms. Loosli et al. (1943) investigated the viability of an influenza virus in various atmospheric conditions, and found that the infectivity of the virus declined much more rapidly at high R.H. Similar results were obtained by De Ome (1944) for *Salmonella pullorum*. De Ome found that increase of temperature also increased the rate of loss of viability, and that the combined effect of increasing the temperature and R.H. appeared to be cumulative. This combined effect amounts to an increase of A.H.

The meningococcus is said to be an exceedingly sensitive organism, highly susceptible to drying or cooling. A leading article in THE LANCET (1931) stated that the organism dies out rapidly below a temperature of 71°F. But such a temperature is very seldom reached in English homes during the winter, and anything approaching it is considered much too stuffy ; yet C.S.M. is a winter disease. I know of no explanation for this discrepancy.

PHYSIOLOGICAL EFFECTS OF LOW ABSOLUTE HUMIDITY ON THE RESPIRATORY TRACT

Epidemics of C.S.M. are accompanied by outbreaks of sore throats. It may be that the meningococcus carrier suffers directly from his infection, but the effects of low A.H. on the respiratory tract are worth considering.

When air enters the alveoli of the lungs it has reached body-temperature and is saturated with water vapour. Its A.H. is therefore 43 g. per c.m.—a constant whatever the external atmospheric conditions. The figure is correspondingly raised by a fever. The extra moisture supplied to the air on its way to the lungs comes from the upper respiratory tract, with the nasopharynx contributing the major share. The amount of extra water vapour required depends, not on the R.H., but entirely on the difference between the external A.H. and the constant humidity of the alveolar air.

From this point of view the air of a temperate winter is far from moist ; it dries the nasopharyngeal mucosa much more than summer air, and so corresponds to the air of the tropical dry season. It is possible that the vitality and resistance to infection of the upper respiratory tract are lowered by this drying action, particularly after a rapid fall in A.H., before physiological adjustment has been made.

Thus, in conditions of low A.H. certain airborne organisms have been proved to live longer, and the upper respiratory tract has to supply more moisture to saturate the tidal air. These facts are in accordance with the epidemiology of C.S.M. in both temperate and tropical climates, and of influenza and lobar pneumonia in the instances I have given. If, as I have tried to show, airborne infections are related to low absolute humidity, such infections could possibly be reduced by humidifying the indoor air, particularly in crowded places. It may be useless to attempt this in the absence of double glazing, but the subject would bear investigation.

SUMMARY

I have tried to show that low absolute humidity is an important factor in the spread of airborne diseases.

The evidence is based on a study of outbreaks of cerebrospinal meningitis in the Gold Coast and their relation to climatic conditions. An analysis of an epidemic of the disease in England and Wales and of the influenza pandemic also supports the proposition. Cold dry weather seems to favour the spread of airborne infection in this country.

The infectivity of certain airborne organisms is increased in air of low absolute humidity. Such air also dries the nasopharyngeal mucosa more rapidly and may thereby lower its resistance.

As a preventive measure the humidity of the air in crowded places might be increased where practicable.

I gratefully acknowledge figures obtained from the published records of the Meteorological Office and the Office of the Registrar-General, and from the annual reports of the medical services of Nigeria, the Gold Coast, and the Sudan. I am indebted to Dr. R. L. Cheverton, director of medical services, Gold Coast, for permission to publish the paper, and to Dr. G. A. Knowleden for correcting my results of coefficients of correlation.

DARENTH PARK HOSPITAL

The Care of Mental Defectives

FOUNDED in 1878 as a school for imbecile children, Darenth Hospital has become one of our largest centres for adult mental defectives of all types. It stands in some 168 acres, of which 126 acres are its own farmlands, on a high ridge above Dartford in Kent—an airy site with a magnificent outlook—and houses at present some 1800 defectives, about 700 of them women, and the rest men. It is capable of taking 1443 men and 956 women, but some wards are empty because of lack of staff.

Mr. J. Tizard and Mr. N. O'Connor, who have been studying, in Darenth and other hospitals, the employability of defectives, estimate[1] that more than half the adult cases in such hospitals are high-grade patients ; and that a large proportion of these are young trainable adults and adolescents who may eventually be discharged from the provisions of the Mental Deficiency

---

[1] See *Lancet*, Sept. 27, 1952, p. 621.

Acts. This being so, it is timely to review what has already been achieved, and is being achieved, at Darenth; for defectives are not less individualistic than the rest of us—rather the reverse, in fact—and attempts to train them for industry will hardly be fully successful unless they are preceded or accompanied by sound social training, such as Darenth tries to give.

The aim has always been, as Dr. J. K. Collier Laing, the physician-superintendent, points out in his annual report for 1951, to return the patient, after training, to the outside world, able as far as possible to fend for himself. Discharges in 1950 and 1951 (apart from transfers to other hospitals) amounted to about a third of the new admissions—of which there were 145 in 1950 and 111 in 1951. In addition, over 300 patients were out on weekly parole in 1951, and an average of 192 were on daily licence.

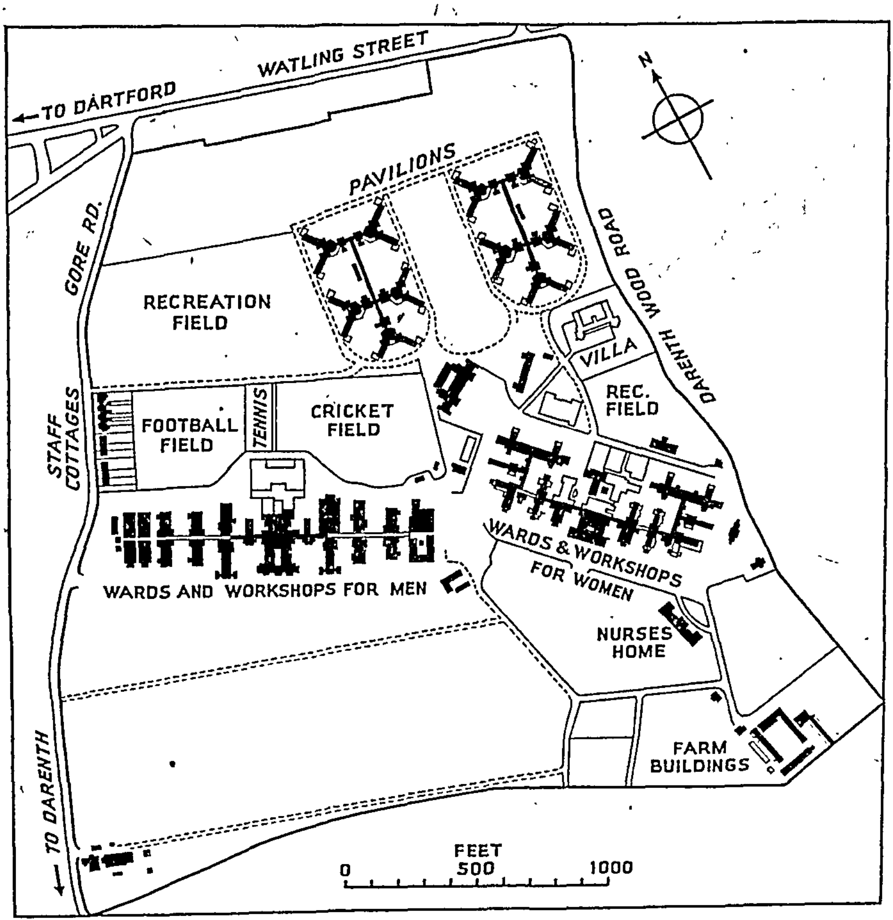
It is thus clear that a very large proportion of Darenth patients live many years or even the whole of their lives in the colony; and it is therefore important to know what opportunities they have to contribute to their own community as well as to the community outside the hospital.

FARMING AND MAINTENANCE

The hospital consists of several large blocks, as the plan shows, set in gardens and farmland. Most of the patients live in open wards, with dormitories attached. Between and round the wards are gardens well stocked with flowers; and these are maintained by a small staff of trained gardeners supported by male patients. It is the experience of the head gardener that most of these patients are able to understand simple lessons on gardening, and that they make very keen workers. Such lessons are given in a classroom on wet days, as well as by practical demonstration in the open. Patients are very decided in their tastes; if they like working in a glass-house, that is what they like, and they will not take readily to other kinds of gardening. If they like open-air gardening, there again they make their choice once and for all. Some of them go out on licence as under-gardeners, and very reliable ones they make.

The chief farm superintendent, who has charge of the hospital acres and herds, also directs farming at the neighbouring hospitals of Stone Lodge (161 acres), Joyce Green (546 acres), and Mabledon Park (20 acres). Smaller acreages of arable land and rough grazing at the Southern Hospital and elsewhere are also under his care. Tuberculin-tested attested cattle herds are kept on all the main farms except Mabledon Park, where pedigree pigs are raised; and large numbers of pigs are bred on the other farms as well. Poultry is mainly concentrated at Stone Lodge and Joyce Green. The annual milk-supply is some 74,000–80,000 gallons, and in 1951 over 165,000 eggs were distributed. Poultry and meat were supplied to the hospitals in the group, and pork was sufficiently plentiful to be supplied to other hospitals as well. The farms also raise all kinds of feeding-stuffs for the stock (amounting last year to 1632 tons) and provide vegetables and fruit for other hospitals as well as those in the group. The work is thus considerable, and provides occupation for many patients in the medium and higher grades of intelligence. They often seem to take naturally to agricultural work, and to be happy in it.

Hospital maintenance provides work for many others. Thus there are bricklayers and painters among the patients, working under skilled craftsmen. These keep the buildings decorated and in repair, besides helping with any new building which is going on. In the carpenter's shop patients help to cut the timber needed by the builders and to make all the wooden fittings used in the hospital, such as stools, benches, and the like. The tinsmith's shop turns out new kettles, coal-scuttles, and dustpans, as well as a great supply of tins and other household articles. There is a mattress-making shop, where hospital mattresses are repaired and pillows made; and on occasion new mattresses are completed. Each stage in the process has to be prepared and presented so that mentally defective workers can understand and master it. The same applies to the upholsterer's shop, where hospital furniture is repaired and re-covered with professional skill and finish—the craftmaster breaking down the various stages in the process so that they become comprehensible to the men working under him. Some parts of it, such as the cutting-out, he must necessarily keep in his own hands, to prevent waste; but nearly all the work can be, and is, done by patients.



The tailor's shop is mostly engaged on repairs, for the men's clothes are bought in bulk from outfitters, and the women make their own dresses. Nevertheless in 1951 this department of Darenth made 12 tweed suits as well as 158 shirts and various coats and pairs of trousers, and was responsible for the repair of nearly 6000 garments and much other work. The matmaking department completed over 200 mats, and repaired as many more; but matmaking goes on all over the hospital, for even disabled patients who cannot leave their ward can enjoy this kind of straightforward handiwork. The same applies to brushmaking, basketwork and which are pursued in several parts of the hospital as well as in their official departments. The shoemaker's department, in

951, turned out 6 pairs of orthopædic boots needed by atients, besides repairing well over 8000 boots and shoes.

The women patients, who cannot very easily be allowed o work alongside the men, are normally employed in the undry (which is very popular), or on needlework. ome hundreds of them have become skilled machinists. hey do all the needlework for the hospital, making resses for themselves and the nursing staff, as well as urtains, bed-linen, rugs, towels, pinafores, underlinen, ight clothes, and anything else which is needed. They ork willingly and happily, but—as always happens ith mental defectives—with plenty of outspoken comment. A thousand nightshirts for another hospital, for nstance, had proved rather a tedious assignment: they were all ready to try something else.

OUTSIDE WORK

Sometimes the output is greater than is needed for ospital maintenance, and sometimes outside orders are illed. Brooms and brushes are always made in excess of the hospital's need, and are sold outside. Unfortunately the market for hand-made brushes has lately allen off. The bookbinding and printing shop is engaged almost entirely on outside work. Much of the bookbinding and printing for the hospitals of the region is done there—a very large assignment—and in addition writing-paper and postcards are cut, and pasteboard folders and envelopes made. Darenth, it seems, bound the file copies of THE LANCET till the pressure of other work made this impossible. In 1951 well over 3000 books were bound there, and more than 500,000 forms printed. Even in a ward of disabled men, some of them blind, handicrafts are pursued with keen interest and pleasure. Some of the best basketwork in the hospital is done here, as well as rugmaking, carpentry, assembly of table-lamps, and other small manageable jobs: even the blind patients knit. The products are sold. In this ward, patients are given plenty of encouragement, but there are no fixed working times; the patients please themselves about how much they do, and they do a good deal.

During the study made by the Medical Research Council team, various other outside commitments were undertaken. Selected groups of patients now help to complete and pack the cardboard containers used by confectionery firms, or file the rough edges from plastic wireless parts. They are well paid for this work, and are allowed to have 5–10*s.* weekly—the exact amount depending on their performance—as pocket-money. The rest of their money is banked for them, and by applying to the matron or chief male nurse they can withdraw sums to spend on clothes, presents, or holidays, or to send home. The prestige of sending home money is, of course, very good for them; but Dr. Laing finds he sometimes has to defend them from rapacious relatives, who, once they find these patients can earn decent wages, do not hesitate to bleed them. In addition to those working in hospital there are, of course, all those working outside on licence—in factories, on building sites, and elsewhere.

LIFE IN DARENTH

The dayrooms of the wards are furnished with comfortable chairs, small tables, hand-made rugs, flowers, and—in the women's wards especially—embroidered tablecloths and cushions. The atmosphere is happy, and the social side well developed. Film shows are given twice a week in one of the three halls, and are also taken on a mobile set to the ward for disabled patients. There are dances weekly, concert parties at Christmas, summer coach-outings (mixed parties where the men escort the women, and all behave with great propriety), a horticultural fête, and a very lively club called the Good Intentions, run by the patients, of which the founder members were all delinquents. This club meets weekly and now accepts those with good records as well as those who have lived down a dubious past; and the waiting-list for membership is long. The spirit in the workshops is cheerful, and the patients enjoy their meals.

Darenth, in fact, is a town in itself, providing work in most of the ordinary trades. Moreover, it is a town with a good community spirit and plenty of social life, and patients who leave often revisit it affectionately for years afterwards. Mental defectives are not necessarily at their happiest when living at large in the community; some of them, at least, are relieved of much anxiety, and of a sense of inferiority, by living in the company of their peers. Some, certainly, are capable of marrying and making good parents, if not very bright ones; but for most of them a single life is desirable. The weight of responsibility which the sex instinct imposes is hard for some of them to bear without the support of an ordered life and friendly discipline. Mentally defective girls, especially, are liable to be exploited when they are not supervised.

All these factors have to be taken into consideration when preparing a patient for a post in industry, or for any other life outside the hospital. Many defectives can be trained to do a straightforward, or even quite a complicated, job as well as the next man or woman; but that may not be all that is needed to fit them for life in the outside world. The main achievement of Darenth is probably the steadying influence which life in ordered friendly surroundings exerts even on disturbed patients. Darenth patients out on licence working with normal men, though they are sometimes teased a little at the outset, are soon accepted and championed by their fellow-workers; and this suggests that they have learned to show their reliable and likeable qualities, even in the face of some prejudice. Since defectives are very sensitive to criticism, this is surely a tribute to their training.

Public Health

The Society of Preventive Medicine

THE new president of the Society of Medical Officers of Health is Dr. Andrew Topping, dean of the London School of Hygiene and Tropical Medicine, and he was installed on Sept. 18 by his predecessor, Dr. W. G. Clark.

In his presidential address, Dr. Topping said that the society would celebrate its centenary in four years. In the first sixty years of its life its members had been engaged in the practice of old-time preventive medicine—improvement of water-supplies, sanitation, and the control of infectious diseases. In the years just before and just after the first world war the changes brought about by the development of local authorities' and personal health services, provision of hospitals, clinics, and dispensaries led to the society gaining many members who were not medical officers of health—a source of criticism of the society's organisation when he joined nearly thirty years ago. It was highly important that more of the junior medical officers should be able to attend meetings, and there was now to be a change in the name of the society which should encourage eligible non-members to join. It was to be called the Society of Preventive Medicine.

As (strangely enough) the first Aberdonian among the 72 presidents, he would deal first with the finance of health and disease. For generations they had been preaching that prevention of disease largely by removing the conditions which conduced to it was not only the logical approach but was also much less expensive than curative efforts. With each succeeding year the costs of curative medicine had been soaring and there seemed to be no limit. Patients suffering from avoidable or easily curable illnesses were encouraged to go to the hospital and the specialist.

Dr. Topping quoted Dr. Hugh Paul's illustration of the cost of curing one blue baby "which would never be a normal child" and of the much better use to which that money could be put in saving the lives of many children by preventive measures and improvement in environment and working conditions. The money spent on tuberculosis sanatoria might be much more effectively used in educating the people in prevention of the disease. Then, regarding prematurity, he was convinced that a large proportion was due to inadequate antenatal care or unwillingness to follow instructions. The modern prematurity unit was most expensive: the right thing to do was to educate the public and so stop the large number of cases. Referring to Bradford Hill and Doll's study of the relation between cigarette-smoking and lung cancer, he said that the publicity had been negligible; it was easier to order another deep therapy unit at colossal cost. The financial position of the country might cause a swing towards prevention as the cheaper expedient, but it would be a pity if this were forced on us by economic necessity rather than by conviction.

The teaching of preventive medicine needed much improvement, particularly at undergraduate level. Little more than lip service was paid to it by some clinical teachers. The teaching of preventive medicine should be done in the ward or (as in the Edinburgh experiment) in the homes of the patients. Habits, environment, occupation, and population trends were most important to the medical student if he was to help the public to understand how to prevent ill health.

As to the tropical countries and the backward countries of Europe, efforts at improving health were foredoomed to failure until these peoples could get improvement in their general economics and agriculture. In many tropical areas there might be lessening of malaria, great improvement in the water-supply, and so on, but for two months of the year there was practically no food. Was it wise to try to reduce infant mortality if one could not at the same time ensure food for the children saved? As a member of a Rockefeller Foundation team in Southern Italy, a pastoral and agricultural area, he had seen children actually starving; there the greatest need was drinking-water, seed, and fertilisers.

It was time, Dr. Topping said, that we pulled out heads out of the sand and faced the difficulty of family spacing. We should aim at improving the quality rather than quantity of our children. Equally obvious was the tendency for the most irresponsible and those in the lowest strata of our population to produce large numbers of children, while higher grades, irrespective of religion, were limiting their families. This general problem was enhanced by the reduction in the infant mortality-rate, the increased expectation of life, and the production by the chemists and biochemists of more and more life-saving drugs. The latter would doubtless before long produce a drug to delay cardiovascular degeneration or even prevent its occurrence. Also it was certain that the cause of cancer would be pinpointed. The biggest world problem facing us was not disease—great enough though this was—and it was not denigration of the preventive services: it was the inevitable consequence of the reduction in infantile and child mortality coupled with the effect on the expectation of life of the new life-saving and life-prolonging drugs.

Blindness in Scotland

There were 9119 blind people in Scotland on March 31, 1952—an increase of 226 over last year's total. In an analysis of this figure the Department of Health for Scotland says that, though the number of blind children has been falling for many years, it has now shown a slight increase. 20 children under the age of 5 were newly registered as blind in the year up to March 31 last—roughly double the average for recent years. An increase in the number of cases of retrolental fibroplasia was partly responsible.

Notification of Puerperal Pyrexia

In his report for 1951 Dr. I. Gordon, medical officer of health for Ilford, says that for some time he has written to doctors in his area who have notified a case of puerperal pyrexia and asked them for the cause of the illness. The regulations do not require the cause to be stated on the form, and Dr. Gordon had been wondering what exactly was being notified.

Of 65 cases notified in Ilford since Aug. 1, 1951, answers have been given for 62; and in 50 of these "the fever was quite unconnected with any infection of the birth passages." In 34 instances the fever was attributed to some disturbance of lactation. Dr. Gordon continues:

> "Who are notifying the cases? In Ilford 63% of births occur in hospital, but 89% of notifications came from the hospitals. Although complicated cases tend to be admitted to institutions, the causes of this fever are so trivial that they might well occur in domiciliary practice. The conclusion we have come to is that the busy family doctor, appreciating the triviality of this notification, neglects to fill in yet another form, whereas the hospital doctor, more bound by rules, and with the help of the temperature chart, does so.
>
> We may assume then that, at any rate in Ilford, notification of puerperal pyrexia has little relationship to infection of the birth passages, as intended, but tends to be merely an indication of minor breast troubles in maternity wards. This is a form . . . that can be easily dispensed with."

W.H.O. Committee on Influenza

At its first session in Geneva last month this committee suggested that the World Health Organisation could help to make information about future influenza epidemics more widely and more rapidly known; for the only prospect of using vaccines effectively seems to lie in identification of the strain of virus at a very early stage in the outbreak. The committee also advised that centres be established to give instruction in laboratory techniques, that the number of research laboratories be increased, and that research publications be made more widely available.

Report on Leprosy

A World Health Organisation report[1] says that estimates of the world's leper population vary from 2 to 7 million. The difficulties of early diagnosis and the inadequate medical services in the most heavily infected areas make it hard to give more accurate figures. The disease is commonest in Asia where there are roughly a million lepers in both India and China. The few endemic foci in Europe are mostly found in the Mediterranean countries, particularly in Spain, Portugal, and Greece. The report comments on the great progress achieved in freeing the leper from the added misfortune of being an outcast; many sufferers are now able to lead a more or less normal life.

New Regulations for Air Travel

After Oct. 1 a person arriving by air in this and other countries which have accepted the provisions of the new *International Sanitary Regulations* will no longer be required to make a personal declaration of origin and health.[2] If such a person is later found or suspected to be suffering from a dangerous infectious disease it may be necessary to trace contacts from the same aircraft. The Ministry of Health has therefore asked medical officers of health to notify such cases direct to the Ministry, so that arrangements may be made to trace contacts through the press and the B.B.C.

Resumption of Slum Clearance

Mr. Harold Macmillan, Minister of Housing and Local Government, speaking at Plymouth on Sept. 24, said:

> "We are hearing a great deal just now about houses which, it is said, are being left unoccupied, or even falling down through lack of repairs. It is said that all the ground we are gaining by building new houses we are losing because an equal number are falling down through decay.
>
> "We must remember that a great many houses ought to be pulled down. Before the war over 60,000 a year were being demolished under slum-clearance schemes. The tragedy today is that people still have to live in houses which would have been pulled down but for the second world war. Nearly 13 years have passed. It is time to take up this work again. It is absolutely vital that local authorities in this country should begin now to consider a resumption of slum clearance. It is a natural function for them—indeed, it is one of their most important—and only they can do it.
>
> "I am often reminded that good agricultural land is being sterilised through building in wrong places. Surely there is no better way of preventing the waste of agricultural land than by using again valuable housing sites which already exist inside our cities and towns. We must build more and more new houses because the waiting lists are still long, but where we can, let us build on sites that are ready-made. Let us start to pull down the worn-out houses and to fill up the toothless gaps in our cities and towns."

In England Now

Running Commentary by Peripatetic Correspondents

WE are told by the pundits that should we be unlucky ough to meet, in a business way, a bullet, a bomb, a bus, the first reaction to the impact will be one of tense surprise. This will be followed by a period of ock and diminished consciousness. The pain, we are sured, will come later.

I was reminded of this sequence of events when I amined for the first time the school bills evoked by nding two children to boarding-school. I have survived e first stage and am now well into the second. Here y mind dwells with irritating persistence on the lidity of the argument which permits the Inland evenue to abstract the part of one's earnings intended r the education of one's own children in order to lucate other people's, leaving little option but the ate schools where there seems to be no room.

My mind wanders round and round this point, but in e great Omar's words comes out "by that same door herein I went." Clearly salaries are not based on ildren's school bills but on some beatific state of lf-sufficiency where "a jug of wine, a loaf of bread d thou" should be the sum total of our worldly eeds. And, as usual, the pundits are wrong: the rocess has been very painful right from the start and ems likely to persist for a long time.

* * *

Two conversations with toddlers have made me realise hat different things the word "hospital" means to the nall child. One bright little chap with mild cœliac isease was strutting about in a man's white pyjama cket which reached to the floor. He hadn't seen me, ough he had heard I was coming. At Sister's suggestion asked him who he was. "I'm Dr. Blank" was the reply, entioning my name. I learned later that he had a tethoscope hidden away, and with this and his white oat he did ward rounds with the other children. Hospital" to him meant fun and games. When I eached home, a small boy of about 3 suddenly appeared n the drive and said he wanted to "look." It appeared hat it was my car he wished to see. After careful nspection his nannie came to say it was tea-time. Have you had your tea?" he said. "Yes" said I. "Where did you have it?" he asked. "Oh, I had my tea t the hospital," I replied. He looked puzzled and rightened and eyed me carefully. "Haven't you been ery well?" he said.

The appearance of a new edition of Martindale's *Extra Pharmacopœia* reminds me that its extraordinary omprehensiveness has made it the basis of a party game mong pharmacists on their festive occasions. Marks re awarded to competitors who can enumerate the onstituents of Mother's mixture (not to be confused with Mother's ruin, which is not indexed), with a bonus or those who know that Mother's mixture originated n University College Hospital—the very fountainhead of Clinical Science. The sophisticated will know, of course, that Trooper's ointment is a trifle demodé. and that Tuba root is designed for the discomfiture of *Musca domestica*, and not for eradicating troublesome musicians. High marks are doubtless gained by competitors who refuse to be trapped into equating Arlacels, Crills, Spans, and Tweens, recognising (from their familiarity with Martindale) that these are *not* parts of a tentative scheme for an international system of weights and measures, but simply non-ionic complex esters or ether esters derived from the hexahydric alcohol, sorbitol.

* * *

I suppose that I have known mon cher ami français for some ten years or more. During that time our lengthier conversations seem always to have centred around one topic—the sweet reasonableness of the French language when compared with the hideous complexities of the English. The conversations usually take the form of long, and often rather lame, explanations from me on our apparent perversity in employing several words where the French employ only one. The frequent defeats I suffer in debate have in no way diminished my smug superiority in being part-owner of such a difficult language.

I had the misfortune last week to cut my finger and for a time flaunted a bandage. My friend was concerned: "What is the matter? Tu as mal au doigt?" "Just a cut: not very sore," I replied. His expression changed from sympathy to suspicion. "In French," he remarked firmly, "we use only one word 'mal,' we say 'mal de tête,' 'mal d'estomac,' 'mal au doigt.' Why do you use many words such as sore, pain, ache?" "Different qualities of sensation," I explained airily. "No-one would dream of saying I have tooth pain, always toothache. I should say that an ache is dull, rather persistent, doesn't obtrude into consciousness so much." I was disturbed by a brief memory of a molar some years ago for which this description was about as apposite as Pussy for a Bengal tiger, but I carried on. "The expression 'pain' is, on the other hand, reserved for a more severe, sharper sensation." I felt rather proud of this spontaneous explanation which my friend dutifully accepted. At least he accepted it until that unfortunate morning when my wife greeted us at breakfast with: "Goodness, my shoulder does ache. The pain kept me awake for hours."

* * *

Pigheaded? Well, perhaps I am,
But I'll no ventriculogram.
I do not care
—I may be dull—
For all that air
Inside my skull.
Gosh, how I'd like to swipe
That scientific type,
So ignorant and smug,
Who cheerfully injects,
Regardless of its side-effects,
The latest wonder drug.
Confound his knavish pricks
He'll play no monkey tricks
On me. Neither at this, or any other juncture
Will I submit to sternal,
Iliac, lumbar, or any other infernal
Puncture.
Once and for all, old cock,
You can keep your stellate ganglion block.
No matter how pained you look or how surprised
I'll not be catheterised;
Nor have you the remotest hope
Of passing that sigmoidoscope.
Lastly, I will grant you a biopsy
Neither of skin nor gland.
And kindly understand
I here and now refuse autopsy.

Religion has gained another victory over Science in our family. On Sunday evening I was told, with the assurance of the young: "You know, mummy, you were wrong when you told us about babies growing in tummies. Really God makes them out of dust."

* * *

Under the present set-up medical officers of health seem to be looked upon as survivals who have outlived their time. More popular in the public, as well as the Ministerial, view are those rare fellows—Physicians, Pathologists, Pædiatricians, Psychiatrists—in fact, anyone whose designation begins with the magical letter P. I realise, of course, that we medical officers of health have the D.P.H., but the P, sandwiched away in a qualification, has lost its power, and until we have got a new name we shall never attain any respect from our medical colleagues, our employing authorities, or the public. P must come into this; P is absolutely essential; P is the transformer: P is the touchstone—without which public regard can never come to us. And I think the way is easy and the outcome bright. Let us only make more astute use of our training and experience as experts in hygiene. As specialists in Psanitary Pscience we shall surely deserve well of our P-loving Public.

Letters to the Editor

THE R.M.B.F

SIR,—I shall be grateful if you will give space for an appeal to provide Christmas gifts for the beneficiaries of the Royal Medical Benevolent Fund.

Gifts at Christmas time have a special value and significance, for they make the recipients feel that they are not forgotten and are being given personal help and sympathy.

I hope that subscribers to the Royal Medical Benevolent Fund will spare a little more to help colleagues and their relatives who have fallen on hard times, and that members of the medical profession who do not subscribe to the Fund will do so without delay. Owing to the increased cost of living, as shown by the higher prices of food, fuel, and other necessities, the need for support is greater than ever. Donations and subscriptions should be sent to the secretary of the Royal Medical Benevolent Fund at the address given below, and marked Christmas Gifts.

Royal Medical Benevolent Fund,
1, Balliol House, Manor Fields,
Putney, London, S.W.15.

WEBB-JOHNSON
President.

BUTAZOLIDINE

SIR,—We have read with interest the comments of Dr. Dudley Hart and Dr. A. M. Johnson on the toxic effects of butazolidine (Sept. 20). While we are in agreement with their note of caution about the use of any new drug, we feel that they have been singularly unfortunate in their experiences.

We hope to publish shortly our further observations on butazolidine therapy, but we can mention now that in over 280 cases we have been impressed by the lack of toxic side-effects.

Since using enteric-coated pills we have noticed no gastro-intestinal upset of any kind.

Three patients have developed rashes. Two of these were shown to be due to causes other than butazolidine (in one case an enema and in the other phenobarbitone). Further doses of butazolidine in these two cases produced no eruption. The third patient, definitely sensitive to butazolidine, was also sensitive to a number of other drugs—e.g., morphine, codeine, and iodoform.

Two cases of œdema of the ankles have been seen: one cleared up completely although the drug was continued; the other promptly subsided when the butazolidine was withdrawn.

Two patients have shown transient slight albuminuria which disappeared spontaneously, although the drug was not stopped.

We now use small maintenance doses instead of continued full dosage, and this may be of importance in the avoidance of side-effects.

Glasgow Royal Infirmary.

R. A. PEEBLES BROWN
J. P. CURRIE.

SIR,—We have used butazolidine in 50 cases of rheumatoid arthritis, with symptomatic relief of varying degree in all but 2 patients; 2 other patients relapsed to their former state after a few days though they were still receiving the drug. Despite its efficacy, the toxic effects of butazolidine have been so frequent, and in 2 cases so severe, that we no longer regard its routine use as justifiable. Complications included 5 cases of maculopapular eruptions, 3 of generalised œdema, and numerous instances of œdema of the feet and ankles. 2 patients, in particular, gave grounds for serious concern.

1. A patient treated with butazolidine developed a maculopapular rash followed by fever and purpura. At the height of her illness various neurological disturbances appeared, including paralysis of the left leg with an extensor plantar response, and incontinence, from which she has made only a slow, and so far incomplete, recovery. These features were regarded as the outcome of a hæmorrhagic myelitis.

2. Another woman developed dryness of the mouth, with enlargement of the parotid and submandibular salivary glands, and was found to have complete agranulocytosis.

In the second case urgent admission to hospital was necessary for blood-transfusion and chemotherapy, and in both these patients the ultimate outcome is still uncertain at the time of writing.

Most of our patients have been given butazolidine in a dosage of 400 mg. per 24 hours; a few have had 800 mg., but none have had more than this. Toxic effects have occurred at both dosage levels. If our cases are grouped with those recently reported by others, it is seen that these complications may be expected in about a fifth of all cases treated, and they include, in addition to the examples already mentioned, gastritis, melæna, and hæmatemesis. It is to be feared that some such disasters are inevitable if this drug is used enthusiastically and extensively without the strictest control.

Brook General Hospital,
London, S.E.18.

DAVID LE VAY
PETER WILSON.

SUCCINYLCHOLINE

SIR,—Recent letters in your columns have dealt with prolonged apnœa after the administration of succinylcholine, and they seem to contradict our assertion[1] that the pseudocholinesterase level of the serum determines the extent and duration of response to the drug. One of them [2] has already been answered,[3] and it was pointed out that, even with a normal pseudocholinesterase level, neostigmine will prolong the response to succinylcholine because it inhibits the enzyme.

Dr. Durrans's careful observations on thiopentone (Sept. 13) are of considerable interest, but we cannot accept his implication that thiopentone and hyperventilation are the real causes of prolonged apnœa after succinylcholine. In collaboration with Mr. L. W. Hall, B.SC., M.R.C.V.S., of the Royal Veterinary College, we have established that raising the pseudocholinesterase levels of the plasma of animals under treatment shortens the duration of apnœa after succinylcholine.

Further, one of us (P. W. S. G.) was given 10 mg. of succinylcholine chloride intravenously without previous thiopentone or any premedication. He was thus able to assess consciously its effects. The depolarising reaction in this instance was most unpleasant; there were spasms of muscle groups, arching of the spine, inability to lift the head, spasm of the pharyngeal constrictors, and an apnœa lasting 40 seconds. The pseudocholinesterase level of the serum was 82 units (the level is defined as 1 unit when 1 ml. of serum liberates 1 µl. of CO_2 per minute from an acetylcholine-bicarbonate buffer solution). We then raised his pseudocholinesterase level to 122 units by intravenous administration, and 10 mg. of succinylcholine chloride was again injected without thiopentone or premedication. This time there was virtually no depolarisation, and it was possible to raise the head, lift the eyelids, and breathe freely. The only subjective experience was a transitory sense of heaviness. We feel that these observations confirm our findings that the response to succinylcholine depends on the level of [illegible] in the plasma.

Dr. Reid and [illegible] 27) measured whole blood cholinesterases in five patients who had responded to succinylcholine with an apnœa of only 5 minutes; the values varied from 113 to 125 "cholinesterase numbers," determined by the method of Aldridge and Davies.[4] In two patients in whom apnœa lasted for

2. Mackay, M. L. *Ibid*, July 19, 1952, p. 145.
3. Lehmann, H. *Ibid*, July 26, 1952, p. 199.
4. Aldridge, W. N., Davies, D. R. *Brit. med. J.* 1952, i, 915.

5 minutes the values were 91 and 94 respectively the normal range is 80 to 129). Thus they found only n insignificant difference in enzyme levels. We suggest hat the failure to obtain bigger differences was due o the fact that they measured the cholinesterase activity f the whole blood. The determination of whole-blood holinesterases was designed to discover early stages of nsecticide poisoning. The relevant insecticides lower he activity of both the pseudocholinesterase of the plasma and the true acetylcholinesterase of the red cells. The conditions encountered in clinical practice, he chief of which is liver disease, affect the pseudocholinesterase of the plasma only, and the true acetylcholinesterase in the red cells remains unaffected. Thus the measurement of whole-blood cholinesterases is as unsuitable in this instance as a determination of whole-blood potassium for the measurement of changes in the plasma-potassium concentration. In our cases, to which several more have been added since the publication of our paper, the true acetylcholinesterase was normal throughout, but the pseudocholinesterase of the serum was materially lowered—a fact which would not have been obvious had we performed our estimations on whole blood.

We feel therefore that there is no reason for altering the view that the response to succinylcholine is dependent on the level of pseudocholinesterase in the plasma.

INTERNAL MEDICINE AND INTERNIST

SIR,—The very successful second International Congress of Internal Medicine (the Congress of Internists) lately held in London has raised the question of the significance of the terms "internal medicine" and "internist"—terms in general use on the Continent and in America, but less familiar in this country where they are regrettably confused with the designations "general medicine" and "general physician."

In fact, during these recent years internal medicine has developed as a specialty in its own right, its development being based on the new physiological knowledge of the functions of regulation and integration of the living being. This development is also due to a reaction against the intensive analytical spirit fostered by other specialties, a spirit not always conducive to effective treatment.

As Sir Russell Brain, president of the congress, has said, the various specialists today consider the whole man by departing from their special angle, whereas the internist first considers the whole man and proceeds later to the detailed examination of special parts. Actually the procedure of internal medicine—as applied by the typical Continental professor of clinical medicine—is more complex, because we cannot know the whole without knowing the parts, and we cannot know the parts without knowing the whole. The internist, using intuitive artistic powers, at first obtains a conception of the patient as a whole. He then proceeds to a detailed examination of the parts, using the precise rational scientific method. In the course of this analytical exploration some facts emerge which modify the conception of the whole patient, and this initiates further researches, and so on, until the precise conception of the whole individual patient is reached. The internist, in fact, passes dialectically—to use the term applied by Plato to the supreme method of knowledge—from the whole to the parts and from the parts to the whole, with the object of a superior synthesis, which is the real diagnosis.

It is obvious that in his detailed exploration of parts the internist may need the help of other specialists, in the same way as other specialists, including surgeons, may need the help of the comprehensive intellect of the internist. The difficult problems of medical practice can only be approached through team-work. A sharp division between medical specialists is impossible. There are specialists—for example, neurologists and cardiologists—who more and more adopt the internist point of view, and there are internists who lean in their studies towards a special aspect, particularly that relating to metabolism, endocrinology, and psychosomatics. At all events, the rise of the internist is an interesting factor in our stirring intellectual times.

London, W.1.
A. P. CAWADIAS.

RENAL FUNCTION

SIR,—Your annotation of Sept. 6 on Diurnal Excretory Rhythm deals with a physiological phenomenon which cannot be explained in terms of the biochemical concepts generally accepted today. Previously I have argued strongly against the current biochemical interpretation of anuria, and I believe that current explanations of renal function may prove equally unreliable.

As evidence of the postulated mechanism of sodium transport, too much significance has been attached to the recovery of a hypotonic urine (on only two occasions definitely, I believe) from the proximal tubule by the method of microdissection (Walker et al.[1]). Platt[2] has recently thrown doubt on the figure of an 80% obligatory reabsorption of water and electrolyte from the proximal tubule; and the independent observations of his team,[3] of Brodsky and Rapoport,[4] and of Wirz, strongly suggest that a mechanism exists by which water, electrolyte, and possibly other dissolved substances are secreted into the distal tubule. We can in fact no longer follow complacently the prevailing school of thought on the function of the proximal and distal tubules. This school emphasises tubular function, under hormonal control, as dominant in urine production, and tacitly assumes the paramount importance of the suprarenal and pituitary—to the exclusion of the glomerular mechanism in this connection. But two facts militate strongly againt this view. The first is that glomerular filtration can be shown, in certain circumstances, to play the leading part in urine formation.

In support of this I would cite Bykov's[5] experiments on his conditioned dogs subsequently hypophysectomised, in which reduction in urine volume could have been caused by diminution in glomerular filtration-rate alone.

Lauson,[6] by injection of albumin into a nephrotic patient caused a rise of water and salt excretion—too immediate a rise to be ascribed to any cause other than the increase in glomerular filtration-rate which accompanied it.

Shannon[7] has shown that, in the dog with diabetes insipidus, dehydration reduces the glomerular filtration-rate and with it the amount of water excreted.

Secondly, the hypothesis of maximal tubular transport has been seriously challenged. For example, Black, Platt, and Stanbury[8] have shown that hyperventilation, or previous low-sodium diets, effects sodium excretion in a way which is incompatible with the postulated tubular maximum.

The shortcomings of the prevailing ideas are evident, as I have said, when we try to explain the diurnal rhythm, wherein the change from lying down to standing up provokes a 10% reduction in the glomerular filtration-rate but withal a 70% drop in salt and water excretion. As the rhythm, in health, affects the output of both water and sodium chloride, it must, *if hormonal,* reflect suprarenal function alone. But Professor Borst[9] has produced unchallengeable evidence that, without variation in the glomerular filtration-rate, this rhythm occurs also in Addison's disease, where suprarenal function is in abeyance. Hence it cannot be a hormone effect.

[7] Shannon, J. A. *J. exp. Med.* 1942, 76, 371.

[8] Black, D. A. K., Platt, R., Stanbury, S. W. *Clin. Sci.* 1950, 9, 205.

The corollary of this finding is to be found in certain of Harvey L. White's[10] animal experiments. By explanting the bladder trigone he was able to get samples of urine from the two kidneys under varying conditions, and he found that a certain degree of constriction of the renal artery on one side did not reveal its presence when inulin and *p*-aminohippurate (P.A.H.) clearance determinations were made a few days later. On the other hand, the sodium and water output on that side was reduced by half. This reduction could not be ascribed to a circulating hormone, for the opposite kidney's excretion was increased by a similar amount; so we are left to conclude that the change must have been largely intrarenal and related either (1) to the renal blood-supply, (2) to the load delivered to the tubules, or (3) to some of the blood being presented for clearance to nephrons other than those in the cortex. Of these three possibilities, the last is most likely because of the inappreciable change in the filtration-rate. It has been established that stimulation of the renal pedicle experimentally will cause partial or total diversion of the intrarenal blood route. There are no experiments so far, that I know of, that have tested the possibility that juxtamedullary nephron activity is associated with cortical activity in physiological conditions of diuresis or in experiments such as this. Their collaboration may affect clearances of inulin and P.A.H. in much less degree and much later than water and electrolyte excretion.

In pathological states the Trueta or Oxford mechanism operates differently. The cortical blood-flow is diverted, in stages, to the juxtamedullary area. Clearance figures —especially if the extraction ratio of P.A.H. is integrated[11] —could support the thesis that moderate stages of the "shunt" take place in moderate hypertension, while more advanced (and acute) degrees of shunt are associated with acute glomerulonephritis and with toxæmia.

In conclusion, may I express my belief that the current conceptions of renal function, and their general acceptance, are preventing progress? They have discouraged, and are still discouraging, research into the function of a major mass of renal tissue—the juxtamedullary nephron apparatus—whose place in the renal scheme they have altogether failed to explain.

A CHEAP SURGEONS' CAP

SIR,—Thirty-five years ago Sir Holburt Waring insisted to his housemen, dressers, and nurses that no hair should be visible inside the theatre; cannot dandruff fall from the eyebrows? To the survivors, the fisherman's jersey bonnet described by Mr. Howkins in your last issue can appear as a mere gesture.

In the interests of economy, a grocer's paper bag would offer more complete covering.

Sherborne, Dorset. JOHN WHITTINGDALE.

THE SPRUE SYNDROME

SIR,—Your representative who reported last week (p. 624) on the discussions that took place after the main papers at the Second International Congress of Internal Medicine, is to be congratulated on being able to summarise the many facts which each speaker attempted to crowd into the five minutes allocated to him. There is, however, one error which I think I should point out. I see that I am quoted as having said that a patient with sprue who did not respond to folic acid improved rapidly when he was given penicillin injections in addition. In fact, I think it more likely that the response was to vitamin B_{12}. The case has been reported (*Brit. J. Nutrit.* 1952, 6, 320). I apologise for taking up space with this letter, but the problem of the effect of antibiotics in megaloblastic anæmia is a complex one, and I do not wish to add further to the confusion.

Department of Medicine,
University of Edinburgh. RONALD H. GIRDWOOD.

CLINICAL STUDY OF ADRENOCHROME

SIR,—Adrenochrome, the red oxidation product of adrenaline, has wide therapeutic possibilities. While in some parts of the world a good deal of work is being done on the physiology, pharmacology, and clinical applications of adrenochrome, elsewhere it has elicited little interest beyond the study of its rôle in the chemistry of melanin formation.[1] [2] Clinically its use as an oxidation catalyst to maintain the efficiency of diabetic labourers in Germany during the late war is well known.[3–5] Adrenochrome and its derivatives, such as the -monoxime, -monosemicarbazone, and -monophenyl-hydrazone, are also known to be powerful hæmostatic agents.[6–8]

The physiological properties of adrenochrome are almost the same as those of adrenaline, except that it has not the same cardiovascular action; for in hypertensive animals it is a hypotensive agent. This leads one to believe that the effects of adrenaline, apart from its sympathomimetic and hyperglycæmic actions which are immediate and short-lived, must be due to the action of the adrenochrome produced in vivo. It has even been suggested that adrenochrome is the real metabolically active material of the adrenal medulla.[9]

To gain a clearer idea of the rôle of adrenochrome as an A.C.T.H. stimulator, the urinary 17-ketosteroid excretion and urinary uric-acid/creatinine ratio were estimated in two people who received injections of adrenochrome 1 mg. once a day.

While there was a slight rise in urinary uric-acid/creatinin ratio, the rise in urinary 17-ketosteroids was neither pronounced nor constant; and in one case (V. S.) there was eve a fall of 20%. This was thought to be due to the transien nature of the A.C.T.H.-cortisone *stimulation,* the effects o which were probably nullified in the course of the next twenty four hours. Hence repeated stimulation was *tried* by givin 1·5 mg. of adrenochrome every five hours for four injections and urine was collected for twenty-four hours from the first injection. There was a definite rise, *not only* in the urinary uric-acid/creatinine ratio, but also in the total 17-ketosteroid excretion (2–3 times the normal value).

These findings, and the fact that eosinopenia and lymphopenia were produced by adrenochrome, show that it has a stimulant effect on the pituitary-adrenal axis; and it can reasonably be expected to benefit conditions where A.C.T.H. and cortisone are known to help. Unlike

drenaline, it does not have any undesirable cardiac ffects, and this makes it more safe for clinical trial as ' poor man's cortisone." Further work is in progress.

Madras. V. SRINIVASAN.

ANTITHYROID ACTION OF P.A.S.

SIR,—We read with interest Dr. Librach's letter of Sept. 13. In a recent paper[1] we have shown that patients treated with salicylates have much higher blood-cholesterol levels than they had before treatment, and in most cases figures similar to those obtained in hypothyroidism are reached. These changes are similar to those found in patients treated with A.C.T.H. and cortisone.[2,3] Wolfson et al.[4] thought the rise was due to the development of hypothyroidism; they demonstrated that both A.C.T.H. and cortisone lower the plasma-bound-iodine level and decrease the radioactive-iodine uptake of the thyroid. To this phenomenon they gave the name corticogenic hypothyroidism.

The clinical and pathological changes during treatment with salicylates are similar to those found during hormone therapy, and we think that the probable reason for the rise in serum-cholesterol levels is the production of a corticogenic hypothyroidism. All the instances found by Dr. Librach during treatment with *p*-aminosalicylic acid can, we think, be explained on a similar basis.

Hackney Hospital,
London, E.9.

L. BERNSTOCK
A. FREEDMAN.

CALCIFEROL IN PULMONARY TUBERCULOSIS

SIR,—Dr. Jackson (June 7) claimed to have conducted a controlled trial of combined calciferol and chemotherapy. I pointed out (July 26) that his six weeks' observation was of limited significance. He agreed (August 9) "for the sake of completeness, it would have been better had a longer course been given." Having admitted the incompleteness of his own observations, his suggestion that I produce what he claimed but failed to produce—an adequate controlled trial—is somewhat irrelevant.

Attention in pulmonary tuberculosis today is rightly centred on the major advances in the fields of chemotherapy and surgery. The basic problem of resistance to the tubercle bacillus remains, however. The purpose of my publication was to present a hypothesis, supported by suggestive clinical observations, bearing on the effect of calciferol on the cellular response of the host. Calciferol remains the only known substance without antibacterial action which accelerates the healing process of a tuberculous lesion. Its action in lupus is unquestioned, and I still claim to have produced suggestive evidence that its action on pulmonary lesions is essentially of the same kind. Its mode of action is surely a subject worthy of experimental and clinical study.

New Delhi, India. J. FIELDING.

"EUGENICS: GALTON AND AFTER"

SIR,—Your review of Sept. 13 does not, I think, do full justice to this important and extremely interesting book by Dr. C. P. Blacker. You say that it would be a mistake to regard the book as a detached and academic survey: "It is written from a personal standpoint which many do not share." In my view, it would be difficult to find a book dealing with such controversial subjects as the measurement of intelligence, birth control, and the Lysenko controversy—to mention only three—written in a more objective manner. I do not know what the personal standpoint is to which you refer, but I would suggest that when a reviewer uses such an expression in criticising a book, he should, if he is fair, indicate the nature of the bias which he believes to exist.

University of Sheffield. JOHN PEMBERTON.

FILARIASIS IN SOUTH SEA ISLANDS

SIR,—You have been so kind as to give an annotation (Sept. 20) to our recent work on filariasis in Fiji, and we are grateful for your remarks on the claims of the non-periodic Pacific variety of Wuchereria to specific rank.

You did not, however, refer to the work of Prof. J. J. C. Buckley, which forms an addendum to our report, in which he has pointed out differences in the morphological features of this Pacific filaria—for instance, the smaller size, and distinctions in the outline of the head and formation of the tail of the female (lack of terminal bulbous swelling) which differentiate the Pacific filaria from *W. bancrofti*. This, if confirmed, should form the basis of a new species—*W. pacifica*. We are emboldened in making this claim by the consideration that the adult of *W. malayi*, another distinct human filaria, which is universally accepted as a valid species, differs in only very minor, and as yet unconfirmed, details from the type species—*W. bancrofti*.

London, W.1.

PHILIP MANSON-BAHR
W. JOHN MUGGLETON.

THERMOMETERS

SIR,—I am surprised that in your annotation of Sept. 13 you condone the placing of clinical thermometers in patients' mouths. Thermometers used exclusively in the axilla do not need to be washed, and the danger of their acting as fomites is slight. Furthermore, the risk of personal injury should they break is less than in the mouth.

My custom is to leave the thermometer in the axilla for at least five and often ten minutes. No time is lost by doing this, as I insert the instrument at once on meeting the patient if it seems likely that the temperature should be taken. In infants and small children I use the groin. During nearly nine years of practice, not one patient has crushed a thermometer.

You go on to discuss the designation of the different types of clinical thermometer in relation to their speeds of registering. I agree with your remarks, but not with the suggestion by the Association of Scientific Workers that there should be only one standard clinical thermometer. May I suggest that there is not really any difficulty in designating the third ("slow") type of thermometer? As far as the purchasing public is concerned, there could be "rapid thermometers," "medium thermometers," and "thermometers."

Uarán Mór,
Gaillimh, Ireland.

SEAGHÁN UA CONCHUBHAIR.

POLIOMYELITIS AND SANITATION ON TRAINS

SIR,—The disposal of human excreta on long-distance trains by discharging it on the line is an offence to all principles of hygiene and decency; yet this system obtains everywhere, even on Pullman coaches, and we are still adjured not to use the lavatories when in a station. I was "privileged" recently to view the undercarriage of an excursion coach before cleaning—a sight even more disgusting than it was Augean. Passenger-carrying aircraft have to provide internal sewage disposal, so why not the railways?

It may be far-fetched to suggest that the present system—or lack of system—plays a part in the dissemination of poliomyelitis; but in our present state of knowledge, the only known factor, aside from personal contact, is

Notes and News

THE MINISTER ON THE SERVICE

SPEAKING at Taunton on Sept. 27, Mr. Iain Macleod confessed to an unusual ambition.[1] He would like to be the first Minister of Health to pass no legislation about health. There has been, he believes, too much legislation and too many instructions issued from his Ministry about the health service. "It is about time," he added "we stopped issuing paper and made the instructions work. I want to try to re-create local interest in the hospital and, above everything, to get a complete partnership between voluntary effort and the State. I want to make it fun for people to serve. I want people to work in the Health Service, from the Minister down to the hospital stoker, because they want to be of service to the poor and crippled people of this country. I have set out deliberately to earn, and then to claim, the support of all the health professions in that idea."

MEDICAL RESEARCH COUNCIL OF IRELAND

IN its report for 1950 the Medical Research Council of Ireland describes further trials of the tuberculostatic compounds, B53 and B283.[2] An immediate conversion-rate of 50% has been achieved with B283 in a small series of cases of renal tuberculosis which had failed to respond to streptomycin. The results with pulmonary tuberculosis were not so encouraging, but most of the patients treated with B283 had chronic disease which had not improved with streptomycin and *p*-aminosalicylic acid, and the merits of the drug cannot be properly assessed until it has been tried in a greater number of early acute cases. The national tuberculosis survey, undertaken by the council at the request of the minister for health, has been using its mass-radiography unit to study the incidence of the disease among people in particular occupations. The cortisone clinical subcommittee has directed work on the use of cortisone in rheumatoid arthritis, rheumatic fever, rheumatic carditis, asthma, allergy, blood dyscrasias, Addison's disease, and Simmonds's disease; and a large number of ophthalmological conditions have been treated with cortisone. Particular attention has been given to the effect of cortisone on anuria. Clinical trials of terramycin are also in progress. Some interesting work at the Rotunda Hospital suggests that unsuspected deep thrombosis may be a commoner cause of varicose veins in pregnancy than is generally believed. Some of the other subjects under investigation last year in Eire were the urinary excretion of steroids in pregnancy; the effect of artificially raising the blood-urea levels of patients with peptic ulcer; and the types of influenza virus isolated in the severe epidemic of early 1951.

THE SMOKE NUISANCE

IN his presidential address to the annual conference of the National Smoke Abatement Society, held at Portsmouth from Sept. 24 to 26, Prof. F. E. TYLECOTE, F.R.C.P., spoke of the great damage done to vegetation and property and health by sulphur gases emitted from chimneys. A yearly emission of $2^1/_2$ million tons of sulphur meant "the huge figure of £62,500,000 per annum lost in the air." Mr. E. E. WILKINS, PH.D., reviewed the work of the Fuel Research Board, including tests of a plant for recovering sulphur in the form of ammonium sulphate and elemental sulphur. The only method of recovery hitherto used on a large scale had, he said, been relatively costly because of the enormous volume of gases to be treated and because the resulting product, calcium sulphate, is in a form of no commercial value. If the outstanding technical problems could be solved, the ammonia process was likely to be considerably less expensive than existing processes.

Dr. PERCY STOCKS, whose address is mentioned in a leading article on p. 667, pointed out that the burning of domestic coal yields a cancer-producing substance, benzpyrene. "The statistical facts we have extracted so far fit in rather well with the hypothesis that atmospheric pollution by domestic smoke is an important factor in the genesis of lung cancer, and that tobacco-smoking is superimposed on it as another important factor."

Dr. J. L. BURN, M.O.H. for Salford, said that industrial chimneys were proving less troublesome as time went on, and the chief difficulty today was domestic smoke: it caused at least half the total pollution and an even higher proportion of the worst pollutants such as sulphur and the tarry products which do significant damage to health. The method of creating smokeless zones was a progressive and positive policy, adaptable and flexible to meet the varying need of different areas: "let us demand more experimental areas where the smokeless zone principle can be demonstrated in varying conditions and circumstances, where details of the advantages and difficulties can be revealed. From the experience gained, a decision may be taken as to the wisdom of expanding the zones and in what areas new zones may be established." Having referred to the existing smokeless zones in Manchester and Coventry, and to the rejection by the Minister of Housing and Local Government of Salford's own more ambitious scheme for smokeless zones, Dr. Burn concluded by saying that all concerned in this great problem will have to show more fighting spirit in order to achieve the cleaner atmosphere they desire.

Mr. W. L. MATHER remarked that coal is one of the few commodities which escape taxation, and that "a tax on raw coal would certainly make industry burn it efficiently or not at all." Dr. W. R. MARTINE, administrative M.O.H. for Birmingham, advocated some form of financial incentive for those who play their part in eliminating smoke pollution. This might be provided by a rates rebate or exemption from increased rating, or by income-tax allowance in respect of expenditure on conversion of premises to smokeless heating.

CORNEAL GRAFTING

THE Corneal Grafting Act, which received the Royal Assent in June, came into operation on Sept. 26. Anyone who wishes may now arrange for his eyes to be used after death for this purpose by making a simple signed statement or a request in the presence of two witnesses. Where no express request has been made, some hospitals associated with centres where corneal grafting is done, if they are satisfied that there is no objection on the part of the patient before his death or his relatives afterwards, may authorise the removal of the eyes. Hospitals known to be doing this work include

Moorfields, Westminster and Central Eye Hospital, London; Queen Victoria Hospital, East Grinstead, Sussex; St. Thomas' Hospital, Lond [illegible] ...ited Sheffield Hospitals; Odst [illegible] ...ord Hospitals; Royal Berkshire [illegible] Bristol Ho... pitals; United [illegible] ...m Hospitals; Birmingham an [illegible] ...hampton and Midland Counties Eye Infirmary; Coventry and Warwickshire Hospital; United Manchester Hospitals; and United Liverpool Hospitals.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS

AT the annual dinner of the college, held in London on Sept. 26, the guests were so numerous and varied that Mr IAIN MACLEOD, the Minister of Health, was hard put to it to find anything they had in common beyond the fact of birth. Speaking of the retirement from the presidential chair of Dame Hilda Lloyd—"a splendid surgeon, a magnificent president"—and the succession of Mr. A. A. Gemmell of Liverpool, he pointed out that provincial presidents of the college have so far outnumbered London presidents by 5 to 1. The college, like Parliament, could go to the country for inspiration, but with the difference that it could hope to get it. Mr. C. D. KENNEDY, who later proposed the toast of The Guests, saw them particularly (among other things) as the rare, the common, and the weeds. When he came to enumerate them, however, he left the impression that everything in the garden was rare. Dame HILDA LLOYD welcomed her successor and spoke of the successful tour of Mr. G. F. Gibberd as the first Sims-Black travelling fellow. The Princess Royal's acceptance of an honorary fellowship, she said, would further grace the college, which already has the Queen and the Queen Mother among its fellows. Miss FLORENCE HORSBRUGH and Sir RUSSELL BRAIN responded. Sir Russell remarked that the guests were very happy to be able to leave the obstetrics to their hosts, and to come to dinner knowing they would have nothing to deliver but a speech.

EUROPEAN HEALTH COMMUNITY

IT is reported[1] that the French government is to submit in October to the committee of ministers of the Council of Europe a proposal to set up a supranational health community. The general aim of the community would be to remove economic and political obstacles to the free interchange of knowledge and materials. Its particular tasks might, for instance, include community research programme; the elimination of trade barriers to the interchange of pharmaceutical raw materials; community sanatoria in the Alpine areas of France and Italy; and common action against epidemics. Common rules for vaccination would be implemented and uniform regulations made for the use of some drugs, water control, food inspection, and child care. The rôle of the proposed community would be complementary to that of the World Health Organisation. In the opinion of M. Ribeyre, the French minister of health, a community of States of comparable development, such as those of Western Europe, could be granted more authority over its members than they would yield to one encompassing the whole globe.

BRITISH SURGEONS IN INDIA AND CEYLON

Two surgical teams recently left this country for India and Ceylon under the technical coöperation scheme of the Colombo Plan. The equipment which both teams have taken with them is also being provided as a part of Britain's contribution to the scheme.

At the request of the Government of India, Mr. Robert Roaf, F.R.C.S., lately orthopædic surgeon to Liverpool Royal Infirmary, will set up an orthopædic department at the Irwin Hospital, New Delhi, and undertake clinical teaching there. He will be assisted by two physiotherapists, and it is hoped that a prosthetic technician will join the team soon. They will spend two years in India.

Last winter Mr. Donald Barlow, F.R.C.S., surgeon to the London Chest Hospital, went to Ceylon to advise the government on the control and treatment of tuberculosis and chest diseases. One of the results of his visit was the formation of a thoracic-surgery unit at Colombo General Hospital, and a British surgical team will now carry on his work. The team is led by Mr. R. Abbey Smith, F.R.C.S.E., thoracic surgeon to the Warwick group of hospitals, and his medical colleagues are Dr. Laurence Mountford, anæsthetist at the London Chest Hospital, and Dr. J. R. Edsall, who will act as registrar. They will be accompanied by a nursing sister and a physiotherapist. The team will be in Colombo for six months.

THE SAFE HEARTH

THE idea that unguarded fires are dangerous is at last beginning to gain ground among the general population; and this means that more people will be buying guards. The pity is that they may buy quite useless guards. With this in mind, the recently formed Birmingham Burning Accidents Prevention Committee asked the makers of guards to submit to them guards of all types. The manufacturers coöperated willingly, and the committee classified the guards according to the degree of safety achieved. They have now published a thoroughly useful leaflet, "Advice on Fireguards" which clearly illustrates suitable and efficient guards for a reflector type of electric fire, a wall electric fire, a portable reflector type of gas-fire, an upright type of electric fire, and an open grate. The manufacturers will probably welcome this guidance as much as anybody else, for it must be dispiriting to turn out guards which are useless for their purpose. It would be an excellent thing if copies of this leaflet could be distributed by welfare centres and health visitors to mothers of families. The Birmingham City Council, with much public spirit, has paid the initial cost of printing, and is selling the leaflets at the low rate of 30s. for 1000 copies. Inquiries should go direct to the Town Clerk, the Town Hall, Birmingham, and should be marked "Burning Accidents Prevention Committee."

A CHIEF IN SPITE OF HIMSELF

As a title, "Father of Crocodiles" does not suggest to the Western mind many of the domestic virtues—nothing, in fact of the warmth, self-abnegation, and sincerity of the best fathers. But different folk have different views; and when certain natives of Bechuanaland, serving with the British Army, and far from home in the Lebanon, wished to honour their Greek medical officer, Dr. George Spanopoulo, by making him their chief, that is the title they gave him. In a naïve but charming little book[1] Dr. Spanopoulo tells how he first met his future subjects when he was posted to the village of Lobatzi, near Mafeking, and what delightful people he found them. He was on equally good terms with the English officers in the mess, though he thought them shy of showing their feelings—for example, when he happened to kiss one of them goodbye. His own cheerful enthusiasm, as well perhaps as what he describes disarmingly as "the excited gestures so typical of my race," must have won him many friends, and certainly gained him the devotion of his Bechuanaland patients. He describes affectionately their loyalty, honesty, and simplicity, their passion for castor-oil, and the solemnities with which they initiated him into his new rank. "From now on, Sir," the interpreter told him impressively, "you are our respectable chief so far from our native land. You will have all our respect and love." Not every doctor has such a tribute paid him.

CANADIAN SURGICAL TEXTBOOK

AT a dinner held in Montreal on Sept. 12, with Dr. Gavin Miller in the chair, copies of the first Canadian surgical textbook were on view. Edited by Dr. H. F. Moseley, assistant professor of surgery at McGill University, the *Textbook of Surgery of the Royal Victoria Hospital, Montreal*, contains contributions from many members of the staff, and the line drawings are by Miss H. McArthur of the department of medical illustrations. Copies were presented to Dr. Gavin Miller, to whom the book is dedicated, to the Principal of McGill University, and to others who had contributed to its publication. Speakers described it as a piece of teamwork animated by loyalty to Dr. Miller as head of the department of surgery at the hospital.

University of Durham

On Sept. 27 the degree of M.B. was conferred on K. S. Dawes.

Royal College of Physicians of London

Lord Moran will deliver the Harveian Oration on Oct. 17, at 3 P.M., at the college, Pall Mall East, London, S.W.1. The oration is entitled Into the Past.

Royal College of Surgeons of England

The Thomas Vicary lecture will be given by Mr. V. Zachary Cope at 5 P.M. on Oct. 30 at the college, Lincoln's Inn Fields, London, W.C.2. The subject of the lecture is William Cheselden and the Separation of the Barbers from the Surgeons.

Royal College of Obstetricians and Gynæcologists

On Sept. 27 the Princess Royal visited the college to receive the honorary fellowship. She was presented to the fellows by Prof. Andrew Claye and Miss Gertrude Dearnley and admitted by Dame Hilda Lloyd, the president. In her reply the Princess said that, though the college was still young, the value of its contribution to medical and surgical science could not be estimated. The specialist knowledge it had placed at the disposal of doctors and midwives thoughout the world enabled them to give to expectant mothers confidence and a feeling of happy security at a time when they were most needed. The careful teaching of mothercraft, too, she was sure, would show its influence by ensuring a generation of healthy, contented babies.

On Sept. 26 the following were admitted to the membership:

Lily Arratoon, Janki Devi Arora, J. L. M. Bean, Anil Chandra Bhoumik, A. D. H. Browne, G. H. Burgess, G. G. Champion, Sivaccolunthu Chinnatamby, G. R. Clare, J. F. Correy, N. K. Crooke, G. E. Cummins, A. M. Dawson, R. D. De Vere, D. T. Dodds, C. P. Douglas, Robert Dowie, Sunit Kumar Dutt, Joseph Firth, Aileen C. Foley, M. S. Forrest, W. T. Fullerton, R. L. Gadd, D. F. P. Gordon, W. J. Gordon, J. J. Handler, Alexander Hunter, Daphne M. E. Kayton, R. D. Macbeth, I. A. McDonald, Margaret W. Macgregor, T. M. McNie, A. G. Mathew, T. P. Magee, P. R. Myerscough, E. P. D. O'Neill, J. G. O'Sullivan, Marjorie M. Paterson, Alexander Persey, G. W. Prueter, Delmont Puflett, Marie Quadros, M. B. Quane, Bibhuti Bhusan Rakshit, Harry Rees, Monica M. A. Reford, C. A. Simmons, E. L. Trott, Mary E. Walker, R. A. Warren, H. B. Watson, J. A. Williams.

Dr. Earl T. Engle, director of laboratories of gynecological pathology and endocrinology, Columbia University, New York, will deliver the Anglo-American lecture for 1952 on Thursday, Oct. 9, at 5 P.M. He is to speak on Trends and Needs in Fertility Research.

Medical Society of London

This society's programme for the first half of the coming session opens at 8.30 P.M. on Oct. 13 with the presidential address by Dr. Cuthbert Dukes. He has called his address Your Good Health. Four discussions have also been arranged for 8.30 P.M. on the following dates: Perils of Blood-transfusion (Oct. 27), Acute Intestinal Obstruction (Nov. 10), Bronchitis (Nov. 24), and Results of Injury to the Pelvic Diaphragm in Women (Dec. 8).

---

[1] Rabaguena, the Father of Crocodiles. Nicosia, Cyprus: Zavallis Press. 1952. Pp. 46.

International Hæmophilia Society

A meeting of this society will be held at St. Pancras Town Hall, Euston Road, London, N.W.1, at 2 P.M. on Sunday, Oct. 5.

London Marriage Guidance Council

A course of five lectures for postgraduate students will be given on Wednesdays at 6.30 P.M. at 78, Duke Street, London, W.1, starting on Oct. 29. Further details may be had from the secretary of the council at that address.

Abortion Law Reform Association

The annual meeting of the association is to be held on Wednesday, Oct. 15, at 6.30 P.M., in the Conway Hall, Red Lion Square, London, W.C.1, when there is to be a discussion on the Prospects of a Parliamentary Private Member's Bill.

Casualties Union

This union is holding its tenth annual competition at 2.30 P.M. on Oct. 5 at Finsbury Borough Council Building Site, Holford Square, London, W.C.1. The competition, which is open to first-aid teams throughout the country will involve accident situations which might occur during large-scale building operations. The address of the hon. secretary of the union is 29, Whyteleafe Hill, Whyteleafe Surrey.

Midland Medical Society

The annual meeting of this society will be held at the Birmingham Medical Institute, 154, Great Charles Street, Birmingham, on Oct. 8 at 8.15 P.M. After the meeting Mr. K. O. Parsons, the retiring president, will give his valedictory address, on the Rewards and Penalties of Partial Gastrectomy for Peptic Ulcer.

The annual dinner will be held on Oct. 22 at the Midland Hotel, New Street, Birmingham, when Sir Allen Daley will give an address on American Medicine Today.

The Professional Nurses and Midwives Conference

The Duchess of Gloucester is to open this conference which is to be held at Seymour Hall, Seymour Place, London, W.1, from Oct. 13 to 17, under the presidency of Lord Webb-Johnson. Dame Hilda Lloyd will deliver the Blackham lecture, and other medical speakers will include Mr. Patrick Clarkson, Mr. N. R. Barrett, Dr. Paul Wood, Prof. D. R. MacCalman, Dr. Wilfrid Sheldon, Mr. D. H. MacLeod, Mr. Myles Formby, and Air Marshal Sir Harold Whittingham. Further particulars may be had from the secretary, Mrs. R. J. Blackham, 1, Garden Court, The Temple, London, E.C.4.

Ministry of Health

Sir Percy Barter, C.B., the chairman of the Board of Control, retired on Sept. 30 after 42 years' service. The Minister of Health has appointed Mr. I. F. Armer, C.B., M.C., deputy secretary of the Ministry, to take over the duties of chairman in addition to his present office. The central administration of the mental health services, other than the work of the Board of Control, will in future be included in the administration of the National Health Service generally.

The Minister also announces that a new division of the Ministry is being created to deal with all questions of remuneration in the health services and with related matters, including questions of staff complements and gradings. Mr. J. P. Dodds, at present under-secretary for finance and accountant-general in the Ministry, will be the under-secretary in charge of this division. He will be succeeded by Mr. A. S. Marre as under-secretary for finance and accountant-general.

Births, Marriages, and Deaths

BIRTHS

CARTER.—On Sept. 17, to Peggy (née Hope), wife of Dr. C. O. Carter—a daughter.

DUNKERTON.—On Sept. 25, at the Louise Margaret Hospital, Aldershot, to Mary (née Cattell), wife of Lieut.-Colonel G. H. H. Dunkerton, R.A.M.C.—a daughter.

HAYWARD.—On Sept. 21, at St. Bartholomew's Hospital, London, to Mary Anna, wife of Dr. Graham Hayward—a son.

PAYNE.—On Sept. 26, at Uplands, Hythe, to Helen (née Mitchell), wife of Dr. Dudley Payne—a son.

RODERICK.—On Sept. 22, 1952, at Princess Beatrice Hospital, London, S.W.5, to Désirée, wife of Dr. John Roderick—a daughter.

THOMPSON.—On Sept. 23, at Gravesend Hospital, to Betty (née Southwood), wife of Dr. Peter Thompson—a daughter.

DEATHS

LAWRIE.—On Sept. 25, John Lawrie, M.B. Edin., 10, Eglinton Crescent, Edinburgh, formerly of Woking, Surrey.

MERRICK.—On Sept. 26, at Kingston Hospital, Horace Townsend Newman Merrick, M.B. Belf., aged 87.

STRETTON.—On Sept. 27, John Weston Stretton, B.CHIR. Camb., F.R.C.S., of Lea Grange, Kidderminster, aged 64.

Diary of the Week

OCT. 5 TO 11

Monday, 6th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5.15 P.M. Mr. Charles Gray: Lumbar Backache.
6.30 P.M. Mr. H. Osmond-Clarke: Major Dislocations.
UNIVERSITY COLLEGE, Gower Street, W.C.1
5.30 P.M. Prof. E. R. Loew (Boston): *Properties of Adr* Blocking Drugs.

Tuesday, 7th

ROYAL COLLEGE OF SURGEONS
5.15 P.M. Mr. Hedley Atkins: Innocent Tumours of Breast.
6.30 P.M. Mr. A. J. Gardham: Right-ilia-fossa Tumours.
BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene, Keppel Street, W.C. Prof. J. Z. Young, F.R.S.: Influence of Language Medicine.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Stre W.C.2
5.30 P.M. Prof. W. J. Hamilton: Comparative Anatomy of Skin.
CHADWICK LECTURE
5.30 P.M. (26, Portland Place, W.1.) Dr. H. E. Magee: Fo as a Health Factor.

Wednesday, 8th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. J. C. Anderson: Hydronephrosis.
6.15 P.M. Mr. J. C. Goligher: Sphincter-saving Resections the Treatm [illegible] e Rectum.
ROYAL SOCIETY OF [illegible] Street, W.1
4.30 P.M. *Section* [illegible] Dr. Donald Wils Spinal Osteoporosis.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. C. W. McKenny: X-ray Technique.
MIDLAND MEDICAL SOCIETY
8.15 P.M. (154, Great Charles Street, Birmingham.) Mr. K. Parsons: Rewards and Penalties of Partial Gastrecto for Peptic Ulcer.
MANCHESTER MEDICAL SOCIETY
4.30 P.M. (University of Manchester.) *Section of Patholo* Dr. R. M. Fulton: The Heart in Chronic Pulmonary Disea
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. F. W. Campbell Twilight Myopia.

Thursday, 9th

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS, 58, Quee Anne Street, W.1
5 P.M. Dr. Earl T. Engle (New York): Trends and Needs Fertility Research. (Anglo-American lecture.)
ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. Everett I. Evans (Virginia): *Management of th* Severely Burned Patient.
6.15 P.M. Mr. R. S. Handley: Secondary Deposits in Mamma Carcinoma.

5.30 P.M. Prof. A. Bradford Hill, D.SC.: The Statistical Approac
ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of Ophthalmology.* Dr. N. Ambache: Physiolog and Pharmacology of the Autonomic Ganglia to the Ey Dr. C. H. Smith: Ocular Actinomycosis.
LONDON HOSPITAL MEDICAL COLLEGE, Whitechapel, E.1
4.15 P.M. Prof. S. P. Bedson, F.R.S.: Twenty-five years Virus Research. (Schorstein lecture.)
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corne S.W.1
5 P.M. Dr. Denis Williams: *Neurology lecture-demonstratio*
FACULTY OF HOMŒOPATHY, Royal London Homœopathic Hospita Great Ormond Street, W.C.1
5 P.M. Dr. W. Ritchie McCrae: Electro-physical Phenomena.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. R. W. Riddell: Superficial Mycotic Infections.
ALFRED ADLER MEDICAL SOCIETY
8 P.M. (11, Chandos Street, W.1.) Dr. L. R. Twentyman Aims and Origins in Medicine.

Friday, 10th

ROYAL COLLEGE OF SURGEONS
5.15 P.M. Mr. R. C. Brock: Surgery of Valvular Stenosis.
6.30 P.M. Mr. G. Qvist: Surgery of Tuberculosis.
ALEX SIMPSON S[illegible]
5 P.M. (The [illegible] dren, Great *Ormond Stree* W.C.1.) [illegible]: Affections of the Skeleto in Children.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. Brian Russell: Pyococcal Infections.

Saturday, 11th

SOUTH EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY
11 A.M. (Preston Hall, near Maidstone.) Mr. A. T. Fripp Joint Tuberculosis.

Thirty-two social workers from all over the world are no attending a two-week course, arranged by the British Counci Twenty-two of the members are holders of United Nations fellow ships or scholarships, and six are *Fulbright* fellows from th United States. The course will introduce them to Britain's soci services before they proceed to studies on their particular subject which include probation work, marriage guidance, reablement, an *public health.*

P.P.S.

PNEUMA, PSYCHE, AND SOMA *

GEORGE DAY
M.D. Camb.
PHYSICIAN, MUNDESLEY SANATORIUM, NORFOLK

HE problem as to why people get ill is only equalled the problem as to why people keep well. If we knew answer to either of these questions we might know w to prevent people from getting ill.

When I was a medical student, good health seemed to the normal state: you were born in good health, and u remained, so to speak, static, in that condition until nething went wrong with your works; and then you re ill. Given time, of course, your works would wear t in any case; and then you died. There was a lot of owledge as to how the works went wrong. Our teachers owed us how to locate the faulty part. This was called a liagnosis." Our textbooks devoted separate chapters sections to each organ and detailed all the different ings that could go wrong with it. For treatment, seases fell into two categories. You either went to a ysician and he would give you something, or you went a surgeon and he would take something away.

There was an intermediate, rather unsatisfactory type patient and he was sent to the electrical department for ysiotherapy. This, I felt was rather like popping a mperamental alarum clock into the oven: it was nazing how often it did the trick. All this worked cely as far as it went; but the reasons given as to why e works went wrong in the first place never seemed nvincing or conclusive.

Why did some people keep well while others got ill? nd how could one prevent the latter from getting ill?

THE CAR, THE ROAD, AND THE DRIVER

Mechanismic somatic medicine did not tell us why eople got ill, nor how they could be prevented from tting ill. Every layman is acquainted with well-ithenticated stories of presumably healthy primitive en turning their faces to the wall and dying for no scertainable organic cause, but just because a spell ad been put on them. Every general practitioner is ruck at some time or another by the way Darby will llow his Joan to the churchyard before the leaves have rned. People behave as no machine has ever behaved.

And so one grew dissatisfied with this mechanismic pproach and shifted insensibly towards the biological pproach. The organism's environment was now taken r more into account, and the concept was widened to clude both the machine and the road it was travelling. t once new light was thrown on the business of keeping ell. Good health became equated with Adjustment to nvironment. Failure to adjust spelled disease. The aintenance of good health ceased to be a dull static ondition and became an exciting dynamic process—as ighly skilled and as dangerous as tight-rope walking. ne was struck with admiration by the way in which one ealt with all the dangers that beset one every moment f one's life. More and more blame was thrown on the nvironment for being so adverse: especially by the acteriologists who were—and still are—discovering nore and more noxious micro-organisms to account for nore and more illnesses. But the question remained nanswered—why did one person remain well while nother got ill, granted that, as far as one could see, hey both enjoyed the same environment?

Then immunology and allergy were discovered. Some eople had more than others. The acid test was that hose who escaped illness must have the higher immunity, and vice versa. People who avoided an illness in January but succumbed to it in February showed seasonal fluctuations in their immunity; and this became linked with vitamin deficiency (which is always a safe bet), hormonic imbalance (which is coming up nicely), and other good scientific dodges. Even so, we did not seem to have got to the root of the problem.

And then came psychosomatic medicine. Now one must be very careful what one says about psychosomatic medicine, but may I try to tell you what I mean by the psychosomatic approach to medicine? You will have to forgive me for quoting myself:

> "It is easier to give a concept of the term 'psychosomatic' than actually to pin it down by a definition. My own tentative conception is that it is analogous to the term 'electromagnetic.' As you will remember well from your 1st M.B. days: in an electromagnetic system it is impossible to alter the flow of electricity without altering the magnetic field. Conversely any variation in the magnetic field is at once reflected in the electrical potential. The two are as inseparable as the heads and tails on a coin, being merely different observable aspects of the same phenomenon. In the same way every alteration in the psyche affects the soma, and vice versa, because (and this is the important and difficult thing to grasp) they are different but interdependent aspects of the same thing: a living individual."

I wrote that five years ago in response to a challenge to define the term, and in the hope that it would be knocked down, and something better and more intelligible reared in its place. But my Aunt Sally still grins back at me unscathed, so I must stick to her.

I will not attempt to define soma, the body, except to remind you that it is alive and so must not be confused with the things you once dissected; and that it manages to keep alive by diligently performing all sorts of complicated chemical processes which are outside our knowledge and control. Indeed it seems so determined to keep alive, so cunning at overcoming obstacles against its survival, so clever at repairing itself when damaged, and so ruthless when reproducing its kind, that it may well have a mind of its own, of which we are quite oblivious. At least it must be granted Schopenhauer's will-to-live.

The psyche, I would diffidently remind you, embraces more than the conscious mental processes: those processes concerned with remembering and forgetting, the evaluation of facts and the arrival at decisions. It includes also the emotions: those dynamic forces which move you to action, or move you to laughter or tears. Sometimes these emotions pop up quite uninvited into the field of consciousness, but more often they remain the back-room-boys—or rather the boilerhouse-boys of the psyche. Often too they seem to derive their force and direction from the somatic "will-to-live."

In my definition of "psychosomatic" I went on to say:

> "The phrase psychosomatic medicine suggests investigating the patient as a whole, accepting the idea that in every condition of life both psyche and soma are affected, and (in practice) treating whichever is handier. . . . There is nothing new in this. But with the advent of every new specific drug, serum, vaccine and operation, the emphasis is shifting more and more towards soma and farther from psyche. General medicine (and surgery in particular) is concerning itself increasingly with ridding a patient of the physical handicap of his illness and getting him back to work. Sometimes this is rather like performing highly skilled running repairs on the car when really it may be the driver who needs attention. Such treatment does not make the patient whole. It is no cure. Psychosomatic medicine, studying the patient as a whole, would seek to make it unnecessary for him to break down."

The concept you see, has widened still further, and our analogy now includes the machine, the road, and the driver. And of course the driver must take his share of the responsibility when things go wrong. Moreover his personality and habits are likely to predetermine the

---

* From the Hunterian Oration delivered to the Hunterian Society on Feb. 25, 1952.

sort of things that are going to go wrong. The chap who drives on his brakes is going to wear out his brake-linings and his tyres. Different horrors await the fools who Never Change Down; who fail to replenish with oil and water; who drive with a load on their minds or a load on their knees, or who attenuate their contact with the reality situation with analgesic liquor. And of course it is true that, drive as carefully and as soberly as you will, no man can escape the fortuitous puncture and its possibly dire consequences.

Similarly, the psychosomatic approach suggests that *Every Man in His Humour*, be it "choler, melancholy, phlegm, or blood," is subject to the appropriate disease; for a humour

> "Doth so possess a man that it doth draw
> All his affects, his spirits, and his powers,
> In their confluctions, all to run one way."

Or in more modern parlance, certain personality types are associated with each psychosomatic affection. Thus there is the asthmatic personality type, the hyperpietic type, the mucous colitis type, the menstrual-disorder type, the arthritic type. Nowadays even our blotting-pads familiarise us with the unhappy facial characteristics of those who tend towards peptic ulceration. An element of predestiny is beginning to creep in. Free choice of ailments is becoming a mockery. And is it entirely true to say that, live he as carefully and as soberly as he will, no man can escape the fortuitous accident and its possibly dire consequences? Are accidents fortuitous, befalling the just and the unjust like rain? No. Certain individuals appear to be more accident-prone than occasion or statistical probabilities would warrant. As a class these individuals are not clumsier or more careless than their fellows. It seems as if every now and then they were assailed by a need to go and hurt themselves.

It may sound fanciful, but I believe that this is a commoner experience than is generally recognised. I fancy many of us can recollect that mood of savage disappointment which is so apt to lead to self-mutilation. When, for example, one is badgered away from the fireside to undertake some long-promised household job of carpentry—a job which in happier moments one would do with zest and no little skill—that is the time the screwdriver slips and lacerates the fingers or the hammer smashes the thumb. It is as if the body rebelled saying, "That'll larn you to try and make me do things I don't want to do." The ostentatious handkerchief wrapped round the thumb mutely relays this message to our Beloved Badgerer-in-Chief as, "Now see what you've made me do." And if only it evoked a low moan, not of sympathy or pity, but of apology and contrition, the situation we feel might be rounded off nicely. But that is conjecture: no man is in a position to say for certain.

GRODDECK'S APPROACH

At this point it is timely to turn to Groddeck and his philosophy. For Groddeck was the father, or perhaps the grandfather, or at any rate the Jolly Uncle, of the modern psychosomatic approach. At the beginning of this century Georg Groddeck, himself a doctor's son, was a physician practising at Baden, who only undertook chronic cases of which his colleagues had despaired. These he treated with bed rest, lots of water inside and out, and strenuous personally conducted massage. During the massage sessions his patients relaxed and talked freely about themselves; and Groddeck listened. It was only after he had cured many incurables and won considerable fame that he discovered that the massage part was not really necessary, except as a means to get the patient talking freely. He listened to his patients, and from what they told him in words and from their response to his ministrations he evolved a psychology similar to that of Freud, except that Groddeck's concept embraced all illnesses, organic as well as the psychoneuroses.

Groddeck's teaching was: "Life is lived by the It." The It was, to him, an entirely unconscious part of the psyche, bursting with energy, and possessing a sort of mind of its own, an entirely irrational, amoral, and primitive mind which was apt to direct this energy to suit its own requirements regardless of consequences. Just like Harpo Marx. The reactions of Harpo are It-directed without any appreciable inhibition or control—apart from the Hayes Office. He will, for instance, chase every pretty blonde he sees, and, if possible, tear all her clothes off. This, by Groddeck's reckoning, is exactly the sort of thing our It—at any rate the male It—would like to do. But our Ego is strong enough, usually, to repress the impulse:

> "Thus conscience doth make cowards of us all....
> And enterprises of great pith and moment
> With this regard their currents turn awry
> And lose the name of action."

Instead of action we may enjoy the idea as a brief day-dream. Or we may be so strongly inhibited that even this satisfaction is denied us because the impulse is never allowed to reach our consciousness, even as an idea.

There is always a confused sort of logic shaping Harpo's activities: the logic of punning, leading, via displacement, towards symbolism. When warned that a document lacks a seal, he triumphantly deposits a live sea-lion upon it. Asked for a secret agent's record, he slaps down a gramophone disc. He dresses in the stage costumes of an operatic tenor and is perplexed and dismayed to find he is still dumb, because the tenor, when he dons these same clothes, sings and sings as if nothing could stop him.

Groddeck's It shows the same paronomasia. The stomach is the one organ which can reject what it does not like: so vomiting is seized by the It as a symbol of rejection, and is called into play whenever anything offends the It—an obnoxious smell, the sight of blood, irritating substances in or around the brain, even fertilised ova establishing themselves in the uterine mucosa. Fainting, that mock-death, is enacted when consciousness of the reality situation becomes intolerable. On an equally superficial level this histrionic symbolism shows itself again and again in conversion-hysteria. The young soldier who has accidentally shot his mate will regain consciousness with a paralysed right hand. His right hand has offended him and he has symbolically cut it off. Spasmodic torticollis is developed by the unhappy Peeping Tom, who wants to look and dare not.

Not all the It's objectives are amoral, antisocial, or destructive. Sometimes our Ego is in complete harmony with our It and then we are 100% happy and efficient. Thus do we enjoy our simpler pleasures: resting when tired, eating when hungry, drinking when thirsty (or even when not), taking violent exercise when restless. Yes, and writing love-letters or the Brandenburg Concertos, painting the *Last Judgment* or the town red, planning 40,000-ton liners or booby-traps for our sisters. For on these occasions we are successfully humbugging the It with counterfeit currency: performing acts of creation symbolising the primal creative act which is the It's deepest craving. At other times, when the It is tugging at the leash in the opposite direction, we are neither completely happy nor efficient. It is then that accidents happen to us, we hurt ourselves or develop trivial ailments. If we fail utterly to come to terms with our It, our It is apt to take charge and play merry hell with us; and it is then that we get really ill. Groddeck warns us that the It always gets what it wants, either actually or in symbolic form. Illnesses and accidents are thus to be regarded—according to Groddeck—as purposefully fulfilling the needs and desires of the It ey may thus be a means for the It to avoid unpleasant ties, to achieve irresponsibility, laziness, and regression a childlike state of dependence upon others. We can y love, attention, and importance by being ill: we arned this in our cots. Illnesses curb our activities. ey break the monotony of life. They punish us.

Patients are seldom free from deep guilt feelings though they have forgotten what they feel guilty out. Why else should they ask: "Why should this ppen to me? What have I done to deserve this?" metimes it is asked with jocular plaintiveness, but more ten it is put seriously, and they proceed to extol their mewhat negatively virtuous lives exactly like the harisee at prayer. Occasionally this recital sounds a tle tinged with regret, as much as to say: "Had I nown this was coming to me in any case, I might not ave been such a good boy."

In all organic diseases, in all accidents, Groddeck ught the same sort of symbolism as is manifest in ysteria. He was always seeking to understand the organ-jargon" of the body, and thus to discover what e It was trying to convey by its charades.

Such was Groddeck's concept. Such was the basis of is therapy. And he was a great healer—not of psychoeuroses and conversion hysterias, but of patients ffering from honest-to-God Conjoint-type organic isabilities. He asked: Why did this patient take ill hen he did? What sort of an individual was he before e took ill? How had life been treating him in the ast? How had he been treating life? What has been eading up to his illness? What has precipitated it? nd why did he take ill how he did? What purpose oes this illness serve? Of what is it symbolic? What s the It trying to tell him?

Instead of prescribing something like a physician, or ubtracting something like a surgeon, he held, as it ere, a mirror up to his patients' nature and made them ee what had previously been concealed from them. His concept, moreover, did furnish a reason, albeit a antastic reason, why people get ill; and taught a rule of ife for the avoidance of illness—namely, "Come to terms ith your It."

But we cannot go all the way with Groddeck. Sometimes we can glimpse the It at work in other people—hen their asthma, their peptic ulcer, or their migraine lay up at what seems to all onlookers to be exactly the ppropriate moment, although never, of course, to the ictim himself. But we cannot stomach the idea that we urselves are puppets, activated by anything so rresponsible, so bafflingly impish and mischievous, as the Harpo-It.

As to listening to one's own It—why, surely the next step would be frank schizophrenia?

The British concept of psychosomatic medicine, in comparison with Groddeck's, is as stolid and respectable as the *Forsyte Saga;* and I am at a loss to know why it meets with such angry or derisive resistance. Of all the many ills that flesh is heir to, Halliday has listed a mere handful—some thirty-odd—as being psychosomatic affections. These, he has shown, possess ætiological features in common: chiefly that these diseases are chronic and given to remissions and recrudescences, and that their onset, remissions, and recrudescences are often determined by emotional experiences; that a particular personality type tends to be associated with each particular disorder; and—his greatest contribution—that the incidence-rate of these diseases in a community is affected by changes in the community's psychosocial setting.

In practice what it boils down to is the investigation of the patient's personality type and his history of precipitating emotional traumata. And most workers find that this is quite time-consuming enough.

But let us not mistake concepts for the truth. With our limited perceptions we can never apprehend the truth about anything. Sitting as we are with our backs to the light, each of us has to interpret the shadow-play on the wall and the echoes of the cosmos according to his experience. Each of us has to select from the cosmic Rorschach blot those details which seem significant, and which allow themselves to be organised into an intelligible system.

The simple concept of a half-crown as an embossed disc of silvery metal is easy to grasp and handle. When it turns into a dust storm of atoms with vast interstellar spaces, or a dance of protons, neutrons, and electrons, or a phenomenon of ineffable wave motion, it becomes unwieldy. We cannot grasp it in the same way. We do not want to grasp it in the same way because it has somehow ceased to be a half-crown, although it may be nearer the truth.

Of necessity we must be prepared to deal with concepts of varying complexity and as mutually contradictory as those of energised particles and wave motion appear to be. Naturally enough we select the simplest that satisfies our immediate needs. In medicine the mechanismic approach suffices when feeding the myxœdematous with thyroid or when whipping out the angry appendix; the biological approach is desirable when dealing with an epidemic of paratyphoid fever; and the psychosomatic approach justifies its vast time expenditure in those chronic diseases whose course is so often influenced by emotional factors.

THE TUBERCULOUS PERSONALITY

When we examine pulmonary tuberculosis in the light of psychosomatic medicine what do we find? Halliday does not recognise it as a psychosomatic affection, and it certainly does not fulfil his sevenfold criteria. Emotional traumata within the 18–24 months preceding the onset of the disease is to be found in many patients. But in enough to make it statistically significant? It is impossible to say. The disease, too, is phasic—it can play cat and mouse with its victim. The course of the illness is definitely affected by changes in the inner emotional environment. But what about the particularity of the personality type?

About four years ago I was determined to find out. By means of the Rorschach projection test administered to 400 consecutive patients admitted to the sanatorium, I tried to ascertain what peculiar personality traits, if any, these tuberculous patients might show in common. At the same time Wittkower was trying to do much the same thing with other groups of patients along different lines. I am sure he would forgive me if I state quite baldly that we both failed to arrive at any conclusions. Tuberculosis did not appear to be the prerogative or predilection of any specific personality type as revealed by psychological testing.

More recently I have set to work from the opposite direction. There were, I reflected, among my friends and acquaintances those who could not conceivably develop tuberculosis—or, if they did, could not possibly die of the disease or allow it to become chronic. They would make a good recovery, and the whole business would merely have been an episode—a few months' stepping aside from the hurly-burly—in their normal span of life. I compared notes with physicians at other sanatoria and found them in agreement with me. So we made lists of these immunes and it became an intensely interesting study, especially when we widened the field to include well-known characters in fact or fiction.

The real giants—the Beethovens, Shakespeares, da Vincis, Ghandis, Schweitzers of this world—are obviously immunes. Of other familiar characters we agreed that Hamlet might have developed tuberculosis—probably the long-drawn-out five-act variety; but not Fortinbras. Richard II yes, Bolingbroke, no. Falstaff in his prime, emphatically no: after his fall—well, possibly. Most of

Dickens's heroes and all his heroines might have fallen into an interesting decline, but most of his comic characters were immunes. Even durance in the Fleet could bring no harm to Mr. Pickwick and Sam Weller, but Mr. Jingle and Job Trotter I feel had a very narrow squeak. Aunt Betsy Trotwood, Mr. F's Aunt, Elizabeth Bennet, Mrs. Proudie, Lady Bracknell, Uncle Toby were all 100% immunes. They might get chills, rheumatism, gout—but not pulmonary tuberculosis. Most of the nice engaging failures in Barrie's plays could have had more than a touch of phthisis, but none of his horrid pitiable successful tycoons could possibly qualify.

Let me go to the other extreme and give you an account of one Tompkinson, a real patient with a borrowed name.

Tompkinson was a farm labourer, but his heart was not in the job. He was left a little money and bought a dreary little haberdashery shop with it, and got married. The shop failed and Tompkinson developed pulmonary tuberculosis. His more successful brother came to his aid, and Tompkinson came under our care. He was not—physically speaking—a very advanced case. He was not ill-nourished: his wife had looked after him well. He was not burning with resentment or frustration, for he seemed to accept his life-long failure quite unemotionally—almost apathetically—as the sort of thing that should be expected to happen to him. With P.A.S. and streptomycin—those therapeutic big brothers—fighting his battles for him his downhill course was delayed; but it was evident from the day of his admission that he could never recover. This death sentence could not be substantiated by his X-ray appearances, sedimentation-rate, [illegible] or assessable data. Not even [illegible]-hand, could the final outcome be so definitely foretold; for we know of those who can pick themselves up from the deepest slough and fight their way out of the toughest spot. One look at the man, a bare five minutes in his company, were as conclusive as a blown fuse.

For my part I found him a most awkward customer. I failed utterly to develop any sort of rapport with him. Now it was clear that he did not know me one-tenth well enough to dislike me with any conviction, so I assumed—quite rightly I later learned from his wife—that he was identifying me with his elder brother, whose bounty had got him under treatment earlier than would otherwise have been possible. Poor Tompkinson had never learned to accept charity. He hated being under any obligation and he hated his benefactors. He also had a sad, forgiving smile which I found intensely irritating. In short, we were not cut out for each other. Post—and, I hasten to add, not propter—hoc, his condition deteriorated patently, he packed up and went home, and died a few months later.

What can it be, I ask, that my immunes have in common, which some others have not got enough of, and in which friend Tompkinson was so sadly lacking? Vitality? Courage? Plenty of tuberculous patients have them in abundance. Indomitability? Steadfastness of purpose? We are getting warmer. I suggest that it is Pneuma, the neglected third party in the Greek triad. Pneuma, the spirit of life which is indomitable, which through faith urges towards a goal not impossible of attainment, and so is triumphant. My immunes, like Prince Hal, were "as full of spirit as a May morning."

It used to be said that tuberculosis was caused by frustration. But that cock will not fight. Tuberculosis is on the decline; frustration, I am told on all hands, is increasing. Frustration can no more cause the disease than can the ubiquitous tubercle bacillus. They can only cause the disease when on one plane the spirit is not strong enough to rise above the frustration, and on another when the body's resistance is not great enough to overcome the invader. This spirit of life must surely inspire every cell in the body: like an allergy. As Dr. Alfred Torrie, paraphrasing St. Paul, has put it: "The body is the temple of the Spirit. The mind is its channel."

There must be a goal and the goal must be possible of attainment. Let me give a thumbnail sketch of a case to illustrate this point.

A young girl, an economics student at a provincial university, developed tuberculosis. She came of an academically brilliant family: father one of the important back-room advisers to the country; elder brother and sister both easy double firsts. The cause of the young girl's breakdown was alleged to be overwork. It was quite true: she had been overworking. But with complete rest, pneumothorax treatment, and antibiotics she did not make the expected progress. Weeks and months went by. She seemed eager to get back to the university, but her return did not seem to get any nearer. Then she divulged that she had found it excessively difficult to keep up with those whom she regarded as her peers. So she was subjected to a battery of intelligence tests, and these showed what she had suspected but had always refused to face. She had not a first-class intelligence; she was a sound second-class, but she had not got the equipment to compete with the rest of the family. This came as a great relief, and her recovery dated from this reorientation. On discharge she took up shorthand and typing, and was gold medallist for the year. She then got a good responsible job in a municipal office. In her spare time she amuses herself with free-lance journalism. Her original goal was impossible of attainment—and her spirit failed her.

There is a case on record where a life was threatened with a railway share, but who has ever before heard of one being saved by an intelligence test?

It is surely failure of the Pneuma which causes the spellbound native to be literally scared to death. On losing his life-partner Darby loses heart and dies. Falstaff, after his renunciation, becomes discouraged and gives up the ghost.

PNEUMA, PSYCHE, AND SOMA

In Greek ideology, Pneuma, the spirit, is something separate and distinct from Psyche, the mind, and this would excuse us for not discovering it in our psychological tests. . . . And so now we arrive at the concept of an indivisible triad of body, mind, and spirit—Pneuma, Psyche, and Soma, "P.P.S." This approach to medicine might, I humbly suggest, be revived after centuries of desuetude. Elsewhere I have likened body and mind to two horses in double harness, sometimes in opposition, sometimes in harmony, interdependent in that if one be lamed the other must suffer disability. Now we have installed a driver of the chariot—Pneuma, the spirit which urges the whole unit forwards, guiding it to the light. If the Pneuma fail at his job, all will soon head for disaster—or come to a standstill.

Plato had this all worked out in 434 B.C. Let me refresh your memory of the *Phaedo*:

> "Let the figure be composite—a pair of winged horses and a charioteer. The human charioteer drives his in a pair and one of them is noble and of noble breed; and the other is ignoble and of ignoble breed, and the driving of them of necessity gives a great deal of trouble to him. . . . The right hand horse is upright and cleanly made, he is a lover of honour and modesty and temperance. The left hand horse, heedless of the pricks and of the blows of the whip, plunges and runs away giving all manner of trouble to his companion and the charioteer whom he forces to approach the beloved and to remember the joys of love."

Now is not that our Harpo again? Groddeck's It! Socrates called him the Appetites. Perhaps we should call him "body mind" in our modern parlance?

It is odd how we have neglected the spirit all these years. Presumably when medicine was divorced from the Church the apothecary-surgeon seized upon the treatment of the body and the mind; while the parson was left with the cure of souls, and he was never called in to see the case until his rivals had failed. And by always being put in to bat last on a very poor wicket, his powers have naturally dwindled. Then, too, that ridiculous controversy of Science versus Religion did not help. Like any sincere argument by the tone-deaf that music did not exist; it was invalidated from the start.

But at the back of my mind I still have Tompkinson on my conscience. Even if all this high-falutin' rigmarole be true, how is it going to help him? Can the Church lp him? Well, in the first place he may not like rsons any more than some people like doctors; and en not all parsons are alike in their outlook. Some em to be abandoning the spiritual discipline for the ore exciting playing-fields of psycho-analysis. If they n combine the two without losing their bearings I am uite sure they can be great healers. I once tried to llaborate with a young padre over a patient. I said, This man looks to me like a very unhappy man who is lost his faith in everything." The young padre id, "He looks to me like a manic-depressive." I alised that we were both trying to pass the buck.

Tompkinson was lacking in Spirit? Can Spirit be nparted where it is lacking, fortified where it is weak? f course it can. In battle a wavering line of troops, in e darkest days of the war a whole nation, can be llied and inspired by the voice of a great leader. Once velve dispirited villagers slunk into a room and were ansformed into the stuff martyrs are made of.

A PLACE IN THE COMMUNITY

The basic trouble with Tompkinson was that he was n "isolate," and I feel that his only hope might lie in eing initiated into a group. It would not matter much hat the group was, be it a bench of bishops, Masonic, r even the Brick Lane branch of the United Grand unction Ebenezer Temperance Association, so long as was a group of appropriate size where his absence or ailure to participate made a difference to everyone else n the group—in fact, to the group as a whole.

While I was in general practice I was involved each winter in producing Gilbert and Sullivan operas in one village and in training a madrigal society in another village. The participants in these different groups never got ill—during the season of activity at any rate. Absenteeism from rehearsals was exceptional even in the 1929 and 1932 epidemics of influenza when I was visiting more than half the cottages in the neighbourhood. We never postponed a show. We never played an understudy—in fact we never bothered to rehearse understudies. At that time I claimed that singing was prophylactic, but I am drawn to the conclusion that any group of people happily engaged in some purposeful creative activity maintain a high average of health. As any Service medical officer can confirm, the morale of a unit can be measured by the smallness of its sick parades. Out East it was the browned-off troops who suffered from desert sores—not the crack regiments in the line, who were making history.

Have we now at last a hint as to how to prevent people from getting ill?

Every sanatorium physician can see group therapy taking place before his very eyes without any intervention on his part. The more a patient identifies himself with the sanatorium group—without surrendering his individuality—the more strength does he derive from it. The problem of indolent tuberculosis has engaged my close attention for some years—the patient who hangs fire for months and months without responding at all encouragingly to all the many treatments that are tried. The vast majority do eventually get well. There is a sort of crisis, maybe without benefit of temperature variation, a turning-point, after which the progress seems just as assured as the stagnation had been previously. After this turning-point nothing can stop them getting well, it seems. Before then it is quite certain that any importunate interference would be met with disaster. I think we all have to confess about some of our major mishaps: "I operated before the patient was ready to get well."

This turning-point, I am convinced, is often brought about by the sanatorium setting and rarely by the medical attendants. But the sanatorium group could not touch Tompkinson. He did not give it a chance. Supposing he had, of his own volition, decided to make a pilgrimage to Lourdes? That in itself would have been a miracle. The miracle of Lourdes, it must be emphasised, is not the complete cure of bodily ailments: this has only happened to 200 patients of the 68 million who have been reported on—a matter of 0·003%. The miracle of Lourdes is the change in the personality of the many who make the pilgrimage. They come back with a changed attitude towards their illness or their incapacitation—an attitude of active acceptance, with an eagerness to help others achieve the same happiness. They have triumphed over their disease. But I have a strong suspicion that this miracle begins the moment the patient decides to set out. A patient sets out to see his doctor in hope maybe, but driven by fear; a pilgrimage is an act of faith, with hope, but with no such compulsion of fear. But is this journey really necessary?

You will be asking, Does this fellow advocate yet another branch of medicine—Pneumo Psycho Somatic Medicine—with textbooks and glossy-covered monthly journals of its own, subscription 20 dollars a year; a further chair with professor on its seat; a further three-month course for the medical student with a question in the conjoint finals? I am not advocating anything. I am merely suggesting that sometimes (when we have the time) it might pay us to look at an all too familiar patient with a new approach—no, not a new approach, a very, very old approach—and ask ourselves: "What is his (or her) spiritual strength and whence is it derived? Is he a church-goer? Has he friends, real friends? Is he an integral part of any community? What is he living for?" It might also be worth while to consult with the parson about difficult, disappointing cases. Perhaps he can approach the patient individually on a religious level where we would feel a bit shamefaced and out of our depth. Perhaps he has some group-activity into which the patient might be fitted. For Mr. and Mrs. Parson between them have their Bible study classes, their discussion groups, their sewing-parties, mothers' unions, boys' clubs, girls' clubs, guilds—some such little gatherings—most days of the week; and they are thus already performing yeoman service in keeping people well and happy. If all these activities suddenly ceased, and there were nothing to take their place, our waiting-rooms would assuredly become even more crowded.

PROLONGATION OF ACTION OF HYPOTENSIVE DRUGS

USE OF POLYVINYLPYRROLIDONE AND DEXTRANS TO LENGTHEN EFFECTS OF HEXAMETHONIUM AND HEXAMETHYLENE BIS-ETHYLDIMETHYLAMMONIUM

F. HORACE SMIRK
M.D. Manc., F.R.C.P., F.R.A.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OTAGO,
DUNEDIN, NEW ZEALAND

BESIDES reducing the number of subcutaneous injections, a method of prolonging the period of action of a hypotensive agent and lessening fluctuation of the blood-pressure would probably be advantageous in various ways. If the fall in blood-pressure lasted longer, the mechanical load on the circulatory system would be less, and more relief might be afforded to the 10% of hypertensive patients whose headaches are at present insufficiently relieved.

In about 1 in 4 or 5 patients the blood-pressure may be well controlled with hexamethonium bromide (H.M.B.) by mouth (Kilpatrick and Smirk 1952), often with a smoother and longer action than can be obtained with injections of simple aqueous solutions of H.M.B. or its homologues. In about 1 in 3 or 4 patients veratrum alkaloids by mouth can be used successfully to obtain a good control over blood-pressure (Smirk and Chapman 1952).

In most patients, however, the best control over blood-pressure has involved subcutaneous injections of simple aqueous solutions of H.M.B., usually thrice daily. With injections of simple aqueous solutions the blood-pressure unfortunately fluctuates widely, rising in the interval between injections, though seldom to the original hypertensive level. Not only is this less satisfactory from the standpoint of the patient but also, without detailed observation (involving in practice the help of trained technicians), it is difficult to adjust the dose in terms of the effect on blood-pressure.

METHODS

The following methods have been used in the Dunedin Hospital in attempts to spread out the action of H.M.B.:

(1) Adrenaline hydrochloride, or the longer-acting adrenaline mucate, has been added to the H.M.B. injection in a concentration of 1/200,000–1/100,000 to retard absorption by causing local vasoconstriction.

(2) Tablets of hexamethonium bitartrate have been administered as a supplement to subcutaneous injections to lessen the rise of blood-pressure between injections and on occasion to diminish the total number of daily injections.

(3) 16% H.M.B. for subcutaneous injection has been dissolved in 25% polyvinylpyrrolidone (P.V.P.) to retard absorption.

(4) 8% 'M. & B. 1863' (hexamethylene bis-ethyldimethylammonium bromide) has been dissolved in 25% P.V.P. for the same purpose.

(5) The absorption of each of the two solutions mentioned above has been further retarded by the addition of 1/200,000 adrenaline mucate.

(6) Doses of H.M.B. by mouth have been used as a supplement to the slow-absorption injections to prolong their actions further.

(7) 16% H.M.B. for subcutaneous injection has been dissolved in 20% aqueous solution of dextran (molecular weight 75,000) to delay absorption.

(8) 10% M. & B. 1863 or 20% H.M.B. for subcutaneous injection has been dissolved in a 20% aqueous solution of dextran (M.W. 20,000).

(9) These solutions have been used also with 1/2000 ephedrine hydrochloride added to delay the absorption further, and hexamethonium bitartrate has been administered by mouth as a supplementary dose to prolong the effect of the injection.

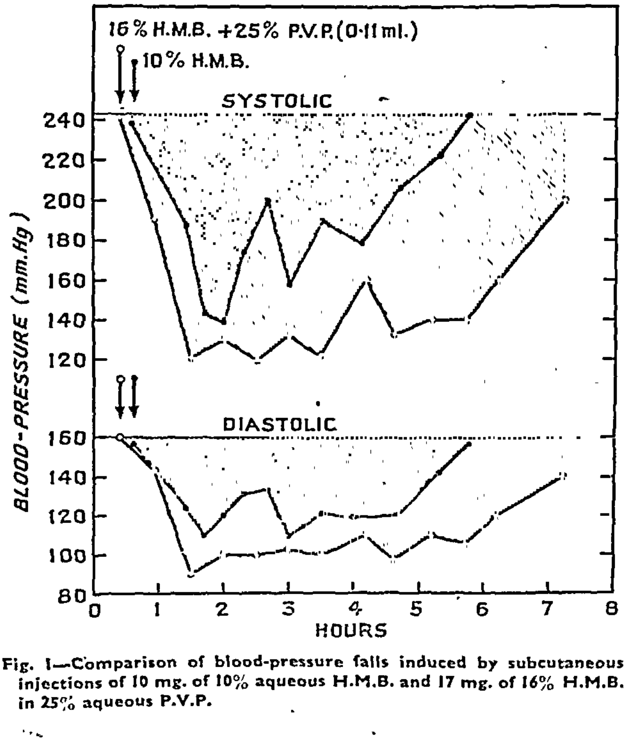

Fig. 1—Comparison of blood-pressure falls induced by subcutaneous injections of 10 mg. of 10% aqueous H.M.B. and 17 mg. of 16% H.M.B. in 25% aqueous P.V.P.

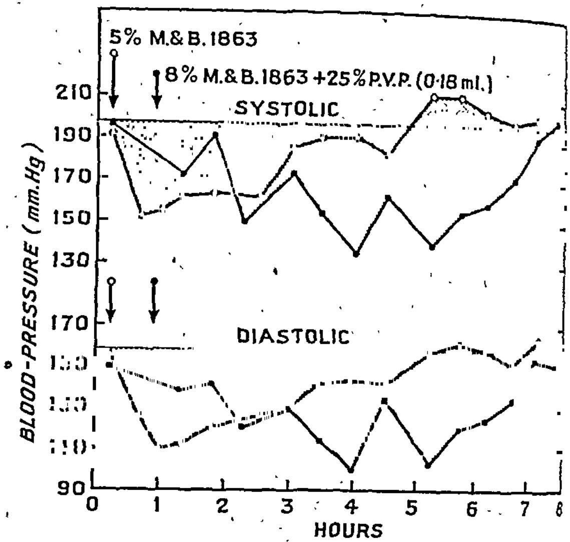

Fig. 2—Comparison of blood-pressure falls induced by subcutaneous injections of 7·5 mg. of 5% aqueous M. & B. 1863 and 15 mg. of 8% M. & B. 1863 in 25% aqueous P.V.P.

Many of the observations on which the present report is based represented, in the first place, attempts to deal with problems arising in the control of blood-pressure in individual patients. No attempt is made to describe the effects of all of the above combinations.

POLYVINYLPYRROLIDONE

P.V.P. is related to the plastics, and in the second world war solutions of it were used as a substitute for human plasma (Hecht and Weese 1943) and are said to have been given to more than 500,000 German casualties. Infusion of as much as 500–1500 ml. of a 3% solution is recommended, and up to 6000 ml. within a few days has been given in emergency. Ill effect appears to be infrequent, but the possibility of storage phenomena (Hueper 1942a and b) cannot be overlooked when large amounts are used for transfusion. There seems to be comparatively little risk, however, in using these substances to slow the absorption of injected material. The total quantity so administered in a year might be no greater than the quantity given in a single infusion of plasma substitute. P.V.P. has already been used as an agent to slow the absorption of insulin (Murat 1949). Much of the P.V.P. first produced had a molecular weight up to 200,000. The material supplied to us is described as having no molecules greater than 100,000, and less than 5% greater than 60,000. Storage phenomena are much less likely with material of lower molecular weight.

DEXTRAN

Dextran is a generic term applied to a carbohydrate polymer of high molecular weight produced by bacterial action and to lower polymers produced from it by controlled depolymerisation. The dextran available to us commercially has an average molecular weight of about 75,000. We have used 20% solutions of this dextran, and of a dextran with a molecular weight of 20,000, as vehicles for injections of H.M.B. and of M. & B. 1863 to retard the absorption of these substances. Solutions of dextran (M.W. 75,000) have been used extensively in transfusions as a substitute for human plasma (Grönwall and Ingelman 1945, Bull et al. 1949, Ricketts et al. 1950). An advantage of dextran is that any unexcreted colloid is likely to be broken down in the body. From the literature available it seems very unlikely that important toxicity will arise from the comparatively small amounts injected subcutaneously. The substance appears to be free from pyrogenicity and antigenicity (Bull et al. 1949) and storage phenomena such as those reported by Hueper (1942a and b) when pectin, polyvinyl alcohol, or methyl cellulose is used for intravenous infusion.

RESULTS

Retardation of Absorption of Hexamethonium Bromide from Subcutaneous Tissues by Adrenaline

It has been mentioned already (Smirk and Alstad 1951) that the addition of 1/200,000–1/100,000 adrenaline hydrochloride or adrenaline mucate may be used to diminish the rate of absorption of H.M.B. from subcutaneous tissue. These amounts of adrenaline are sufficient to cause local constriction of blood-vessels but insufficient to affect the heart or blood-vessels after absorption. A dose of 100 mg. of H.M.B. in 10% solution has a volume of 1 ml., and this contains 0·005–0·010 mg. of the adrenaline salt. The main effect of the admixture with adrenaline is to reduce the depth of the trough of the fall in blood-pressure which ordinarily takes place shortly after the injection. The hypotensive effect of the H.M.B. is diminished if the same dose is used, but this may be offset by an appropriate increase of dose. A typical graph has been published elsewhere (Smirk and Alstad 1951).

In some instances the addition of adrenaline leads to useful prolongation of the action and reduces the depth of the initial trough—in other words, it leads to a more uniform fall of blood-pressure. Reference is made later to the use of adrenaline and of ephedrine hydrochlorides to prolong further the action of M. & B. 1863 when the latter is dissolved in 25% P.V.P. or in 20% dextran (M.W. 20,000).

Retardation of Absorption of H.M.B. or of M. & B. 1863 from Subcutaneous Tissues by P.V.P.

When H.M.B. is dissolved in a viscid 25% solution of P.V.P., absorption is delayed; and, when the dose is increased to offset the slower absorption-rate, a more gradual and prolonged fall in the blood-pressure results. The effects of H.M.B. in simple aqueous solution and in solution with P.V.P. are compared in fig. 1. M. & B. 1863 can also be dissolved in 25% P.V.P., and its action also can be prolonged in this way (fig. 2). At first we used a 16%, but later a 20%, solution of H.M.B. in P.V.P. to limit the volume of injected material. With M. & B. 1863 initially an 8%, but later a 10%, solution was used, these solutions being about equivalent in effect to 16% and 20% H.M.B. respectively, since the M. & B. 1863 is about twice as active as the H.M.B. In a few instances we have used 20% M. & B. 1863 for patients who have required very high doses. This needs a tuberculin syringe if the volume injected is small. In general the duration of effective hypotension is increased from an average of three hours for simple aqueous solution to six to eight hours in the presence of 25% P.V.P.

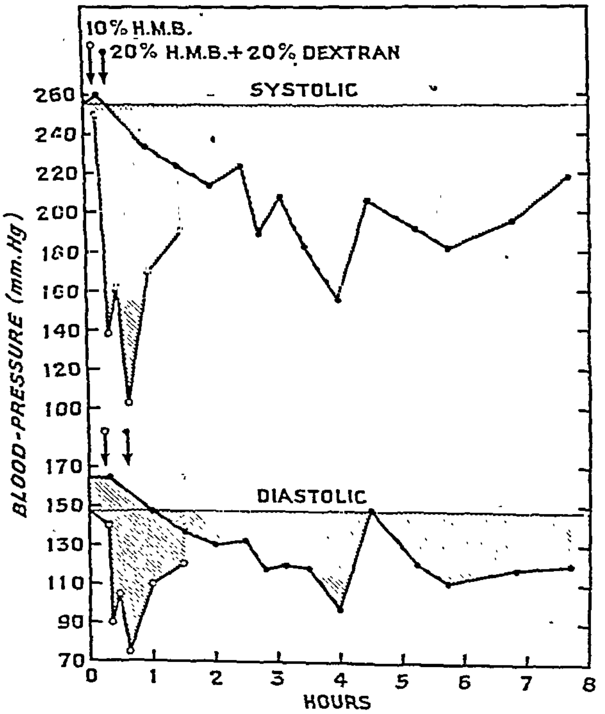

Fig. 3—Comparison of the blood-pressure falls induced by subcutaneous injections of 25 mg. of 10% aqueous H.M.B. and 20 mg. of 20% H.M.B. with 20% aqueous dextran M.W. 20,000.

In this instance the trial with H.M.B. and dextran took place earlier than the trial with aqueous H.M.B.; hence, owing to development of drug toleration, the effect per mg. is greater with the earlier than with the later dose.

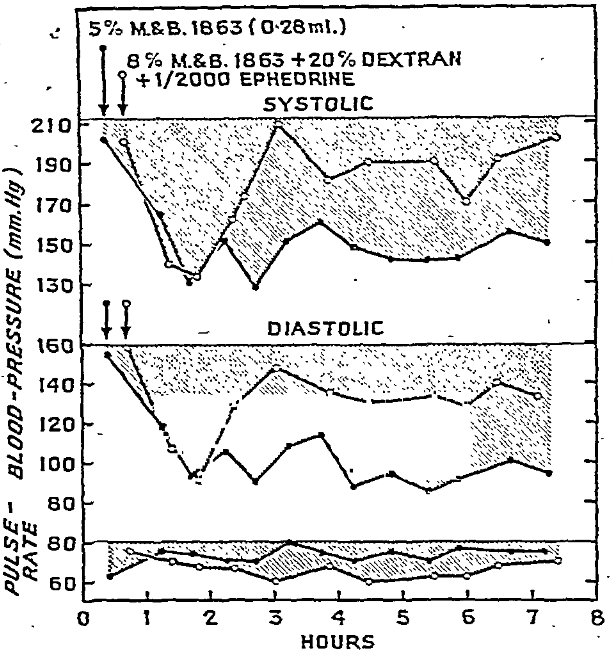

Fig. 4—Comparison of blood-pressure falls induced by subcutaneous injections of 14 mg. of 5% aqueous M. & B. 1863 and 20 mg. of 8% M. & B. 1863 with 20% aqueous dextran M.W. 20,000 and 1/2000 ephedrine hydrochloride.

Retardation of Absorption of H.M.B. from Subcutaneous Tissues by Dextran M.W. 75,000

This was studied in 32 observations on 19 patients. The initial results were confusing because sometimes the H.M.B. solutions without dextran caused a more prolonged fall of blood-pressure than did H.M.B. with 20% dextran. The explanation seems to be that, where absorption is sufficiently slowed, the concentration of H.M.B. in the blood and tissues only rises above the threshold for activity for a short time. Hence it can happen that retardation of absorption may lead to a shorter instead of a longer period of blood-pressure fall. The prolonged action in such cases is only observed when the dose injected is increased until the magnitude of the greatest fall of blood-pressure is the same as with the simple aqueous solution; then the fall of blood-pressure induced by the slowly absorbed preparation is demonstrably prolonged in almost all instances. Unfortunately, in most patients the preparation with dextran M.W. 75,000 caused tender subcutaneous lumps, and it was decided to try dextrans of lower molecular weights.

Retardation of Absorption of H.M.B. and M. & B. 1863 from Subcutaneous Tissues by Dextran M.W. 20,000

Solutions of 16% H.M.B. or of 8% M. & B. 1863 were made in a 20% aqueous solution of dextran M.W. 20,000. Subsequently we changed to 20% H.M.B. and 10% M. & B.

1863. Retardation of the absorption of these methonium salts resulted, of a degree comparable with that already observed with 25% P.V.P. or with 20% dextran M.W. 75,000 as a delaying agent. Most patients find these solutions in 20% dextran M.W. 20,000 only mildly irritant, and the addition of 0·5% chlorbutol lessens pain and serves as an antiseptic. No instances of any toxicity have been encountered, and so far no subcutaneous lumps have been discovered after injections of dextran M.W. 20,000. A comparison of the duration of hypotension after injections of simple aqueous H.M.B. solutions and after solutions in 20% dextran M.W. 20,000 are set out in figs. 3 and 4.

In general the duration of effective hypotension is extended from an average of three hours with simple aqueous solutions to five to eight hours in the presence of 20% dextran M.W. 20,000, and sometimes slightly longer if 1/2000 ephedrine hydrochloride is added (fig. 4).

Combinations of Methods for Improving Control over Blood-pressure Levels in Arterial Hypertension

A more prolonged and uniform decrease of the blood-pressure in arterial hypertension can be obtained in many cases by combinations of methods already described. Thus either H.M.B. or M. & B. 1863 with either P.V.P. or dextran M.W. 20,000 has been combined with supplementary doses of either H.M.B. or M. & B. 1863 by mouth. These supplementary doses, given as the blood-pressure starts to rise again, sometimes extend the period of activity of the methonium salts even when oral therapy alone has been unsuccessful. This is because residual amounts of the drug are present in the body after a subcutaneous injection; hence it is possible to manage with a smaller oral dose, thereby avoiding side-effects.

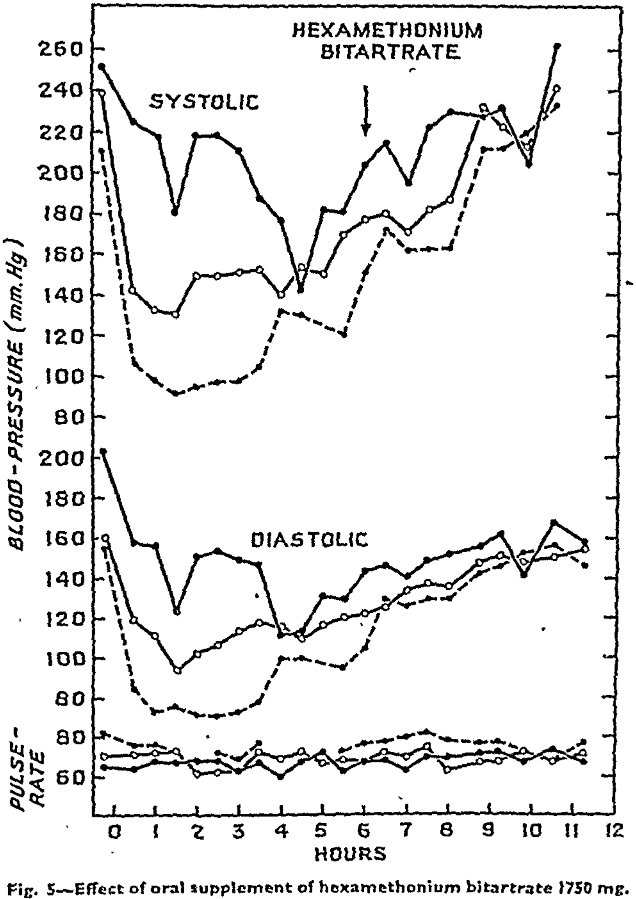

Fig. 5—Effect of oral supplement of hexamethonium bitartrate 1750 mg. to prolong further the action of an injection of 20% H.M.B. 360 mg., 20% dextran M.W. 20,000, and 1/2000 ephedrine hydrochloride. Blood-pressures were read in the following postures: --●--, standing; —○— sitting; and —●—, lying.

The duration of action of H.M.B. or of M. & B. 18 may be extended further by adding 1/2000 ephedrine hydrochloride. The H.M.B. (250–1250 mg.) or hexamethonium bitartrate (350–1750 mg.) was given orally as the blood-pressure began to rise again after the subcutaneous injection. With this combination it is usually possible to extend the fall in blood-pressure from a single subcutaneous injection over a period exceeding eight hours (fig. 5).

Such combinations usually provide a better control than can be obtained by the injection of three doses of simple aqueous H.M.B. Sometimes, however, it is preferable for the patient to accept three well-separated injections to control the blood-pressure during the day and night. The slow-absorption preparations have the advantage of greater ease of control, in so far as the blood-pressure does not vary so greatly in the course of the day, and measurement of the blood-pressure in the standing and sitting postures some two and a half hours after the subcutaneous injection will give some idea of the amount of fall of the blood-pressure provided the patient is not emotionally excited by the visit to the clinic.

DISCUSSION

It has been shown that either polyvinylpyrrolidone or dextrans of average M.W. 75,000 and 20,000 may be incorporated in a solution for subcutaneous injection to prolong the period of absorption of methonium drugs. Further prolongation may be effected by the addition also of 1/200,000–1/100,000 adrenaline hydrochloride or mucate, or of 1/2000 ephedrine hydrochloride. The duration of activity of these slow-acting compounds varies to some extent with the dose administered. With fully effective doses in which the trough of the blood-pressure fall may be only a little above 120/85 mm. in the standing posture, and sometimes 100 mm. or more below the starting blood-pressure, the duration of significant action is about five to eight hours and occasionally longer. When the absorption of an otherwise effective dose of H.M.B. is slowed by injecting it in a suitable vehicle it is necessary to increase the dose to obtain effective prolongation of action. The [illegible] dose can be [illegible] ed determined only by direct trial [illegible] Usually the dose of H.M.B. or of M. & B. 1863 must be raised by at least 30% when transfer is made from a simple aqueous to a slowly absorbed preparation.

The use of oral supplements of H.M.B. when the blood-pressure is beginning to rise again has been shown to make it possible, in some instances, to obtain as good a control over blood-pressure levels by one slow-absorption injection plus oral supplements as has been obtained previously with three subcutaneous injections of the simple aqueous solution. Though this constitutes a gain it is preferable to have two or three injections and a good measure of control than one injection and a more moderate degree of control. Convenient injection times are 8 A.M. and 6 P.M. for two injections, and at six-hour intervals for three injections. Where, however, as in some elderly patients, the treatment is largely symptomatic, the one injection may be preferred.

Polyvinylpyrrolidone is probably safe in the amount used, but a much longer trial will be needed, and initially we have been confining its use to elderly patients with very high blood-pressure and to patients where the great height of the blood-pressure between injections made us feel that any risk of toxicity is smaller than the risk from the blood-pressure rises. With P.V.P. of comparatively low molecular weight, objections may not apply. Theoretical objections to P.V.P. do not seem to apply to the use of dextrans as agents for prolonging absorption from the subcutaneous tissues. Although a dextran with a molecular weight of 75,000 causes local irritation with the formation of lumps, the dextran with a molecular weight of 20,000 seems practicable for the purpose.

SUMMARY

The duration of the hypotensive action of subcutaneous jections of hexamethonium bromide and of M. & B. 1863 ay be prolonged to five to seven hours by dissolving iese substances in 25% polyvinylpyrrolidone or in 20% extran of molecular weight 20,000.

Further prolongation may be effected by addition of local vasoconstrictor (1/2000 ephedrine hydrochloride) o the injection solution.

Even in patients whose blood-pressures cannot be well ontrolled by oral administration of hexamethonium alts, oral administration of hexamethonium bromide hen the blood-pressure is due to rise again may someimes further prolong the action of the injected salt.

When a slowly absorbed preparation is used, the dose nust be increased to provide an adequate tissue oncentration over the extended period.

My thanks are due to Miss M. Poppelwell for secretarial vork, and to Miss J. Rivers, Miss N. Hoggan, and Miss B. Stanton for technical assistance. Messrs. May & Baker Ltd. upplied the hexamethonium bromide, M. & B. 1863, and olyvinylpyrrolidone, and Messrs. Bengers Ltd. and Crookes aboratories Ltd. the dextrans. The expenses of the work vere defrayed in part by the Medical Research Council of New Zealand.

VENOUS VELOCITY IN BEDRIDDEN MEDICAL PATIENTS

H. Payling Wright

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

It has been shown by Wright et al. (1951) that the velocity of venous blood-flow in the limbs of patients after surgical operations varied considerably according to their convalescent régime. In those who were allowed out of bed, with active movements, soon after the operation the venous flow-rate remained normal, or was even increased, in the following days. In those who were confined to bed, on the other hand, there was a gradual slowing of the blood flow-rate, which was apparent by the third day and persisted until the patient was once more up and walking about. These changes were observed in both upper and lower limbs but were far more pronounced in the lower.

An immediate explanation of these findings presented itself—i.e., the enforced rest was responsible for the slowing of the flow-rate in the bedridden patients—and it was with the object of investigating this hypothesis that the present study was undertaken.

METHOD AND MATERIALS

The method, using $NaCl^{24}$ as tracer, for the measurement of venous velocity in the leg was identical with that previously reported by Osborn and Wright (1949). The only deviation from the original procedure was that the patients, being examined in bed, did not have their feet immersed in water before the measurements but were all ascertained to be comfortably warm. Bed-temperatures were found all to lie between 33° and 35°C (Wright et al. 1948).

The cases for this study were carefully selected so that they fell into two distinct groups:

Group I comprised 42 men and women, aged 22–77, in whom cardiac, active respiratory, or renal disease was absent, and whose blood-pressures were normal. Their hæmodynamics could be considered normal and any recorded alterations of venous flow-rate might be directly attributed to their confinement to bed. The diagnoses of the cases in this group were as follows:

Diagnosis	*No. of cases*	*Diagnosis*	*No. of cases*
Duodenal ulcer ..	9	Carcinoma, larynx ..	1
Gastric ulcer ..	8	Carcinoma, stomach	1
Rheumatoid arthritis	6	Hodgkin's disease ..	1
Phthisis (closed) ..	5	Cerebral tumour ..	1
Diabetes	4	Rheumatic fever ..	1
Obstructive jaundice	2	Pernicious anæmia ..	1
Slipped lumbar disc	2		
		Total	42

Each patient was seen within six days of admission to hospital and weekly for three weeks or until he became ambulatory. Only those were selected who were expected to remain in bed for this period or longer.

Group II included 22 patients, aged 39–80, with hemiplegia. They obviously all presented various circulatory abnormalities and impaired hæmodynamics. They offer, however, a second method of assessing the influence of immobilisation on blood flow-rate. Each patient was seen on one occasion only, flow-rate measurements being made on both the non-paralysed and the paralysed legs. Every case therefore acted as its own control, and the comparative velocities in the two legs may be analysed irrespective of any generalised circulatory changes. The paralysed limb represents complete immobilisation, while the unaffected one was moved about voluntarily.

RESULTS

The velocity measurements obtained in the two groups show a significant difference. In group I the average flow-rates were remarkably steady throughout the period of investigation, and correspond closely to those found in normal persons under standard conditions. The day-to-day variations were also similar to those reported in normal volunteers (Wright and Osborn 1952). The results for each three-day period during the first three weeks of rest in bed are set out, with the standard errors of their means, in the accompanying table. It is apparent that the enforced rest caused no appreciable retardation of the leg venous flow-rate in these cases.

Group II, however, shows a different picture. The flow-rate in both legs has been analysed, first to determine whether the unparalysed leg shows any divergence from the normal, and secondly to detect whether the complete immobilisation due to paralysis has had any effect on the venous velocity on the affected, as compared with the unaffected, limb.

It was found that the unparalysed leg showed a slight but constant slowing of the venous flow-rate compared with the normal (4·35 cm. per sec.), a mean of 3·88 ± 0·58 cm. per sec. being obtained for the group. This figure falls near but within the lower limit of normality. In the affected leg, however, a greater retardation of venous velocity was apparent, the mean being only 1·47 ± 0·36 cm. per sec. The probability that the observed differences in the paired limbs was due to chance was found by Fisher's method to be less than 1 : 100 ($p < 0{\cdot}01$). This significant difference in venous flow-rate in the legs of hemiplegic people may be referable mainly to the state

AVERAGE RATES OF VENOUS FLOW IN BEDRIDDEN PATIENTS

No. of days of complete rest in bed	Venous flow-rate (cm. per sec.)	No. of observations
1–3	4·8 ± 0·56	18
4–6	4·3 ± 0·48	16
7–9	4·5 ± 0·52	16
10–12	4·8 ± 0·49	14
13–15	4·3 ± 0·54	9
16–18	4·7 ± 0·54	13
18 +	4·3 ± 0·48	13

of immobility, lack of muscular tone, and atrophy on the affected side.

DISCUSSION

It has generally been believed that complete rest in bed decreases the rate of venous blood-flow in the legs, and that the consequent stagnation is a potent factor in the onset of thrombosis. That venous thrombosis is of common occurrence in medical cases is beyond dispute (Burke 1938, Neumann 1938, Pilcher 1937, Westerborn 1946, Zimmerman et al. 1949), but comparatively few experiments have been made to elucidate the sequence of events which precedes their formation.

Frimann-Dahl (1935), using a phlebographic method, showed that venous flow was retarded in both the femoral and saphenous veins in normal people confined to bed. His observations were not, however, confirmed by Deitrick et al. (1948), who followed the effects of complete immobilisation in four healthy young volunteers. At the end of six or seven weeks in whole-body plaster spicas, the arm-tongue, arm-perineum, and arm-foot times, measured with 'Decholin' and 'Macasol' (Spier et al. 1936), showed no appreciable change over the pre-immobilisation figures.

The direct measurements of venous flow-rate in the legs presented in group I are in agreement with those of Deitrick et al. (1948) since no significant diminution of velocity was apparent during the first three weeks' confinement to bed.

The highest incidence of venous thrombosis and consequent fatal pulmonary embolism occurs among medical cases with circulatory defects (Barker et al. 1941, Lillie et al. 1949). It must be emphasised, however, that in the present study all such patients were carefully excluded, and that the group was composed of people who might be considered as "normal" so far as their hæmodynamics were concerned.

In the previous report (Wright et al. 1951) on patients convalescent after surgical operations we noted a gradual retardation of the flow-rate during the first fifteen days' confinement to bed. Evidently no such change takes place in the medical cases under similar conditions of rest. This may be explicable in two ways: (1) after surgical interference, pain and fear of postoperative complications cause the patient to lie exceptionally still, with respiration shallow and diaphragmatic movement minimal, with the result that the respiratory pump is less effective (such factors are absent in our medical cases); and (2) it can be seen from the list given above that the types of case included here are mainly such as benefit by rest in bed; by the end of the first week they are usually feeling better and consequently are more actively moving about (sitting-up, reaching into lockers, &c.), though still technically bedridden. A similar return to activity occurred rather later in convalescence in the surgical group.

The results in group II show that complete immobilisation apparently does have a material effect on the venous velocity in the legs. In this group the unaffected limb is usually kept comparatively still. This, together with their cardiac condition, which in itself decreases circulation-time (Blumgart and Weiss 1927, Fishberg et al. 1933, Kvale and Allen 1939, Kvale et al. 1939), explains the decreased flow-rate observed in the unparalysed leg. The still greater reduction in velocity in the paralysed leg is probably due to the failure of the massaging action of the muscles on the blood-vessels and to the lack of muscular tone (Wakim et al. 1948), and presents the most extreme degree of slowing due to immobilisation. The mean flow-rate of 1·47 cm. per sec. is considerably lower than that found at any time in non-ambulant surgical patients, whose lowest rate was 2·7 cm. per sec.

In the light of these findings it seems probable that a slowing of the venous velocity is common to cases of cardiac failure and arteriosclerosis, and to postoperative surgical patients, and that the continued high incidence of thrombosis in all these groups depends to some degree on this factor.

SUMMARY

Venous velocity was measured in the legs of 42 medical patients without cardiac complications during three weeks' confinement to bed. No significant changes were observed during the period of rest.

Venous velocity was also measured in paralysed and non-paralysed legs of 22 patients with hemiplegia. That in the non-paralysed limbs was within the limits of normality. In the paralysed limbs it was greatly reduced.

We wish to thank the physicians of University College Hospital and Lord Amulree, director of the geriatric unit, St. Pancras Hospital, for permission to examine their cases. This work was supported by a grant from the Medical Research Council.

THE CONSERVATIVE TREATMENT OF FRACTURES OF THE SHAFT OF THE RADIUS AND ULNA IN ADULTS

HAROLD BOLTON
B.Sc., M.B. Manc., F.R.C.S.
SENIOR REGISTRAR, ORTHOPÆDIC SERVICE, MANCHESTER ROYA INFIRMARY

A. G. QUINLAN
M.B. Lond., F.R.C.S.
SENIOR REGISTRAR, ORTHOPÆDIC DEPARTMENT, NORTH STAFFORDSHIRE ROYAL INFIRMARY; LATE RESIDENT ORTHOPÆDIC REGISTRAR, MANCHESTER ROYAL INFIRMARY

THE treatment of fractures of the radius and ulna i adults is mainly concerned with the restoration of th rotatory function of the forearm. Sound union i adequate alignment and recovery of a full range of movement at the wrist and elbow joints can, in most cases be obtained by either conservative or operative treatment. We attempt to assess the results of conservative treatment in nearly one hundred forearm fractures treated in the University department of orthopædics at the Manchester Royal Infirmary.

HISTORICAL

Before the advent of radiography the treatment of forearm fractures was based on the correction of clinical deformity, followed by the application of two short wooden splints with a firm pad to preserve the interosseous space and with the arm in the mid-prone position (Erichsen 1884). Limited rotation was often ascribed to cross-union.

Treatment with wooden splints continued to be the standard practice for many years. Plaster-of-paris, although introduced as long ago as 1852 by Mathijsen in the treatment of fractures, was not applied in forearm juries, no doubt from fear that rigid encasement of a mb might lead to ischæmic paralysis. From 1929 nwards, following the example of Böhler (1929), the laster cast, applied with due precaution, became the outine method of controlling forearm fractures.

In the early years of the 20th century, operative eduction with internal fixation was practised only by uch pioneers as Lane and Lambotte. In the hands of ess experienced surgeons the wound not uncommonly ecame infected, and the effectiveness of the fixation was sometimes impaired by electrolytic changes round he metallic plates and screws. The latter complication was eliminated by the introduction of vanadium-steel lates in 1913 (Sherman), but it was not until the nvention of the relatively inert molybdenum steel and, ter, 'Vitallium' (a cobalt-chromium alloy), that nternal fixation came to be widely used.

The routine position of the forearm during immobilisaion, which at one time had been mid-prone, was varied in ccordance with special circumstances. Thus certain urgeons argued that all fractures should be held in upination, because this movement was always difficult o restore at the conclusion of immobilisation. Magnuson 1922), on anatomical grounds, recommended that fracures above the insertion of the pronator radii teres muscle hould be held in full supination, and those at or below this evel in the mid-prone position. He also advocated the use of continuous traction with the patient recumbent nd the forearm held vertically. Patrick (1946) pointed out that, if fractures of both bones of the forearm are perfectly aligned in both anteroposterior and lateral adiological views, the degree of rotation must ipso facto be correct. In practice this corresponds to the positions dvocated by Magnuson. Patrick also considered that imitation of rotation in these fractures was due to the spread of callus, hæmorrhage, and fibrous tissue into the nterosseous space, especially from the ulnar side, leading to shortening and fixation of the interosseous membrane. Evans (1945) has introduced a radiographic technique which enables the degree of rotation of the upper fragment to be deduced and thus makes possible a more ccurate correction of rotatory deformity. He points out that merely placing the lower fragments in the correct degree of rotation in relation to the upper fragments is often enough to secure a good reduction.

Most of the modern monographs recommend closed methods of treatment; but open reduction, with or without internal fixation, is regarded as necessary where t is impossible to achieve or to maintain reduction by conservative methods (Watson-Jones 1949, Campbell 1949, Charnley 1950). Carrell (1938) estimated this to be necessary in about 15% of cases. If either of the bones does not unite, a bone-graft can be substituted for the plate. Böhler, on the other hand, claims that, by strong traction—skeletal where necessary—and direct manipulation under fluoroscopic control, closed reduction is possible in all cases, and admits of no failures. All the series of fractures of the radius and ulna treated by closed methods which have been reported, notably by Bagley (1926) and Whipple and St. John (1917), are mainly composed of fractures in children, who present an easier problem. Buxton (1939) reported on 44 cases in adults but gave no detailed results. Evans (1951) also reports on 50 cases, more than half of which are children, without separating the results in the adults from those n the children. This analysis gives 90% "good" results for conservative treatment.

MATERIAL

In many cases in the present series the immediate post-reduction position of the fractures was not fully maintained. Where secondary displacement occurred, an attempt was made to restore the original position by re-manipulation. This was unsuccessful in most cases. Many of them would now be considered suitable for operative reduction and fixation. Advocates of the operative method claim a quicker, easier, and more perfect restoration of function than is obtainable by conservative means. Our investigation of the results obtained in 92 patients treated in 1939–50 by the closed method has convinced us that, as a routine, conservative treatment has many advantages. All the patients were aged more than 21 at the time of their injury, and at least nine months—in most cases much longer—had elapsed between injury and final assessment. Particular attention was paid to the recovery of rotation and to the occurrence of complications.

Age-incidence.—The age-incidence was as follows:

	Age (yr.)						
	20–29	*30–39*	*40–49*	*50–59*	*60–69*	*70–79*	*80–89*
No. of patients ..	10	13	25	16	19	7	2

Sex-incidence.—38 were males and 54 females.

Sites of fractures.—The fractures were in the upper third of the shaft in 10 cases, in the middle third in 38 cases, in the lower third in 41 cases, and at different levels in 3 cases.

Presence of wound.—In 72 cases the injury was a closed one; in 20 cases a wound or wounds were present, sometimes with associated damage to muscle or tendon. In 1 case the tendon of the extensor pollicis muscle had been divided; the tendon was repaired, and a full recovery resulted. In another case multiple severe lacerations in the arm, with division of major vessels and nerves, led to amputation. In a third case there was laceration of the hand with loss of the thumb.

Nerve lesions.—The following nerve lesions were discovered on first examination, and before the fractures were manipulated: (1) ulnar nerve palsy in 1 case, in which the nerve recovered while the patient was under treatment; (2) paralysis of the posterior interosseous nerve in 2 cases, in both of which the nerve recovered in the course of treatment; and (3) in 1 case an associated severe lesion of the brachial plexus with complete paralysis of the arm, and in this case there was no recovery, subsequent amputation becoming necessary.

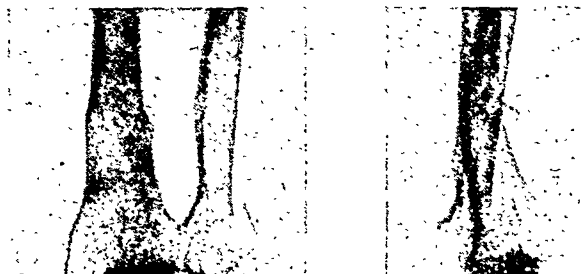

Fig. 1—Fractures of lower quarters of radius and ulna.

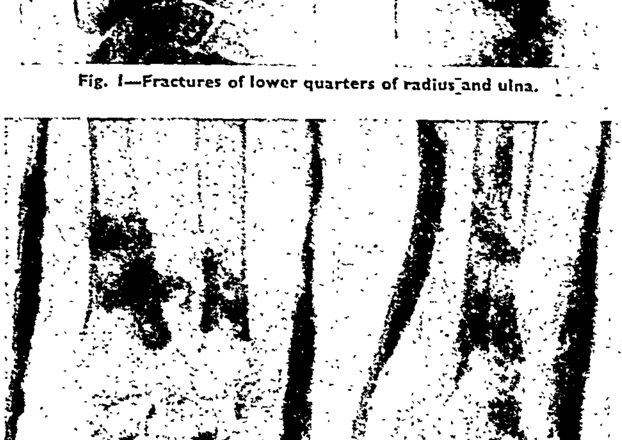

Fig. 2—Same fractures as in fig. 1 after manipulative reduction and plaster fixation.

Delayed complications.—In 1 case a very painful stiff wrist developed after immobilisation, with spotty osteoporosis of the radius, ulna, and carpus. This was regarded as an example of Sudeck's atrophy, and a good recovery ensued under conservative treatment.

TREATMENT

Reduction of the Fracture

These patients were treated by successive senior assistants in the fracture clinic, and at least ten different people have been responsible for the results. This fact seems to eliminate the personal element of technical skill as a factor in achieving the results. In compound injuries, excision and closure of the wound or wounds where necessary, followed by manipulative reduction and plaster fixation, was the routine. Assisted by a [illegible] tractor, or by gauze stuck to the fingers, strong traction was applied to overcome shortening; the ulnar fracture was usually reduced first, followed by the radial fracture. The best position was found by trial and error in different degrees of rotation until a stable position was obtained. This was done with the forearm horizontal and a webbing sling over the upper arm as a means of counter-traction, or more recently by suspending the forearm vertically. In practice the forearm was usually found to lie in full supination for the upper-third fractures, and in the mid-position for those at a lower level.

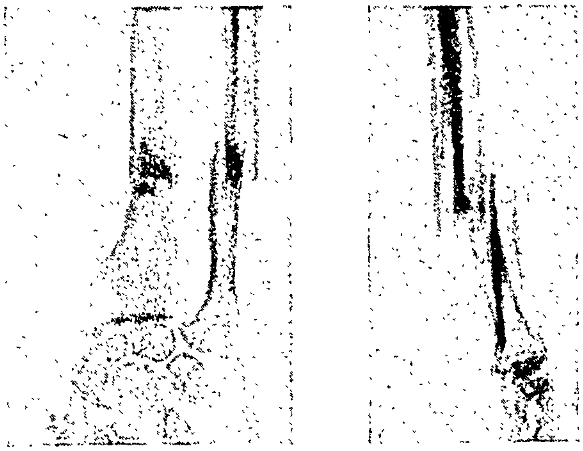

Fig. 3—Fractures of lower thirds of radius and ulna.

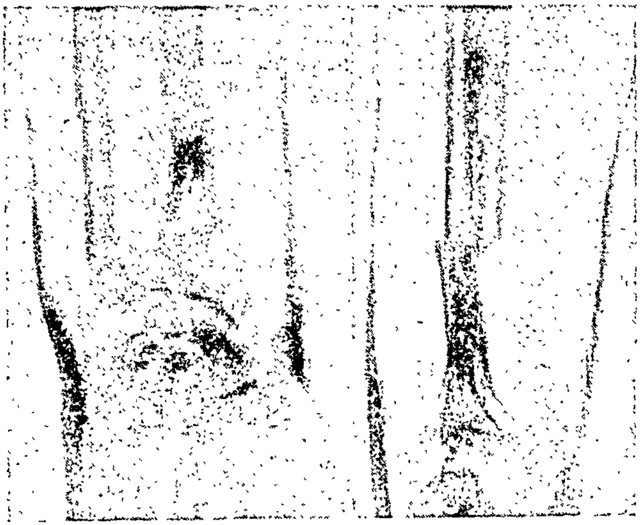

Fig. 4—Same fractures as in fig. 3 after manipulative reduction and plaster fixation.

A lightly padded, moulded plaster cast from the axilla to the knuckles was applied, and the forearm section was moulded into an oval to preserve the interosseous space, and to prevent the radius and ulna from collapsing towards each other during the subsequent immobilisation. The position of the bones was next checked by radiography. We regarded a reduction as acceptable when full length was restored, alignment in each bone was within 5° of normal, and both bones were in contact. In some of the older patients a less perfect reduction was sometimes accepted, especially where a further anaesthetic was undesirable. Plaster fixation was usually maintained with frequent X-ray checks, for 10–12 weeks, or until clinical and radiological tests confirmed that the bones had united. The arm was next supported with a sling for a further few weeks, and function was restored by physiotherapy.

In common with other workers, we found that the difficulty in many cases was not the reduction of the fractures, which was usually easily done, but the maintenance of reduction while the plaster was being applied, and the prevention of redisplacement of the fractures in the early days or weeks which follow (figs. 1 and 2).

In the present series the mean duration of fixation was 13 weeks, the longest 56 weeks, and the shortest 6 weeks. The average is raised by a few cases of delayed union or non-union immobilised for long periods. It was not found necessary to immobilise the fractures of the lower quarters of both bones for longer than 6–8 weeks.

Number of Manipulations

In 74 cases one manipulation sufficed to bring the fractures into an acceptable position; in 16 cases two manipulations were necessary; in 1 case three manipulations were necessary; and in 1 case four. It was often found that re-manipulation did little or nothing to

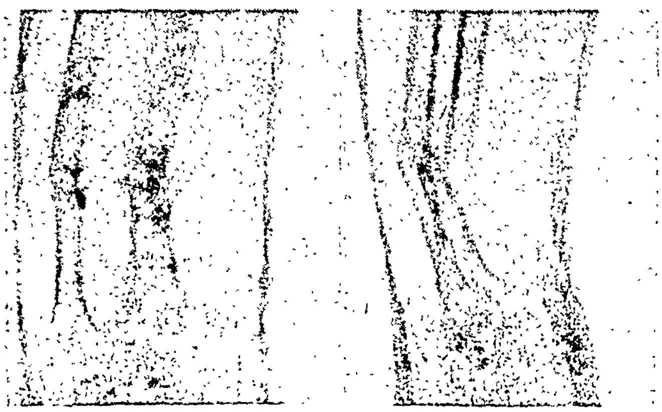

Fig. 5—Same fractures as in fig. 3. Secondary displacement occurred in plaster. This was the best position that could be achieved by re-manipulation. Radiograph taken 9 weeks after injury.

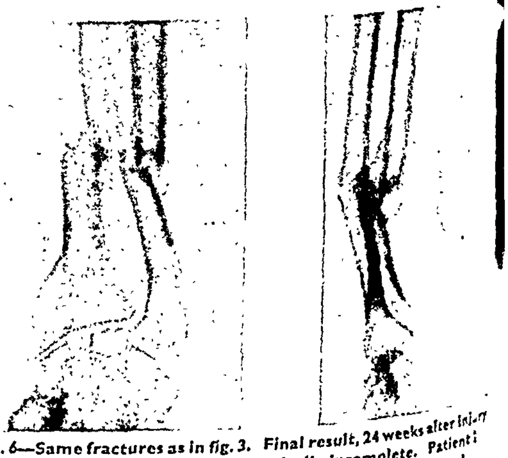

Fig. 6—Same fractures as in fig. 3. Final result, 24 weeks after injury. Union clinically firm but radiologically incomplete. Patient [illegible] full pronation, but no supination. Operation was refused.

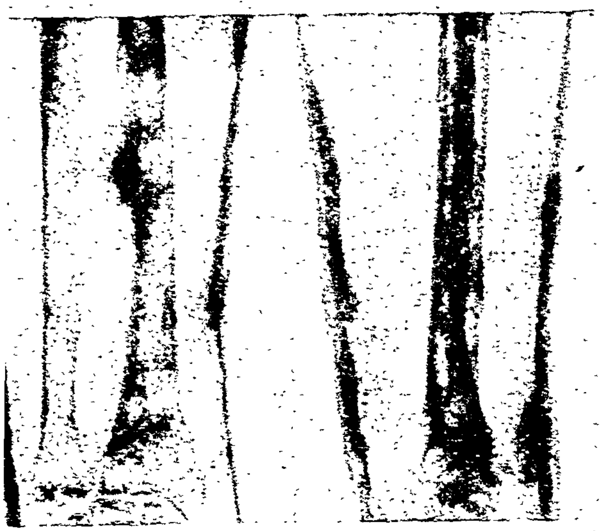
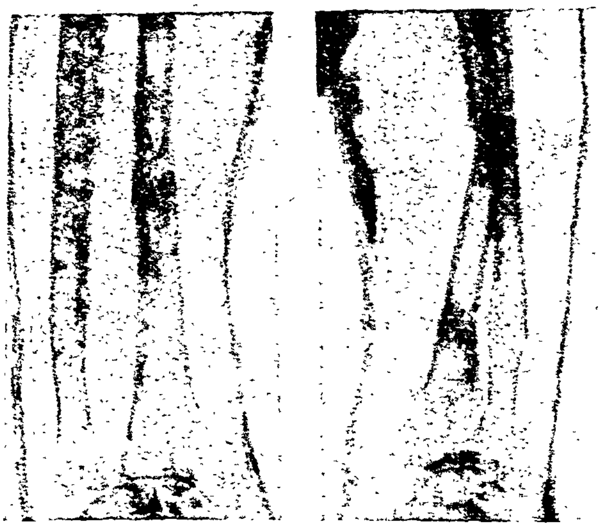


g. 7—Fractures of mid-shaft of radius and ulna after reduction and plaster fixation.



ig. 8—Same fractures as in fig. 7, showing secondary displacement in plaster after two weeks. This was not corrected by re-manipulation. Patient regained a full range of rotation.

improve a position which had originally been acceptable but had subsequently slipped during plaster immobilisation (figs. 3–6). In 14 cases there was radiographic evidence that displacement occurred in the plaster after reduction and was not corrected by further manipulation (figs. 7 and 8). Of these 14 patients 10 regained either full rotation or minimal limitation of a third or less of supination or pronation. Displacement may have taken place in more cases, but it was impossible to verify this point. These observations do not apply to cases where the first manipulation did not produce an acceptable position and re-manipulation to correct this was undertaken immediately.

RESULTS

All the cases have been included except the 2 requiring amputation. Those which developed delayed union, non-union requiring operation, and mal-union necessitating resection of the lower end of the ulna to restore rotation, have also been included, and have been classified as poor results of conservative treatment, in spite of the fact that after appropriate reconstructive treatment the final result in these cases was good. This leaves 90 cases for analysis.

Union

Sound bony union took place in 80 cases. There were 4 cases of non-union treated by bone-graft operations usually within a year of the original injury (figs. 9–12). There was delayed union in 4 cases, in all of which prolonged fixation led to sound bony union with satisfactory results. Mal-union was observed in 2 cases in which there was subluxation of the inferior radio-ulnar joint with severe loss of rotation.

Anatomical Results

These have been subdivided into good, moderate, and poor. Cases with little or no bowing at the fracture site are classified as good. A noticeable but not a gross bow has been classified as a moderate result, and a severe bow as poor. 56 cases were good, 22 were moderate, and 12 poor. It must be admitted that this is a clinical rather than a radiological classification. It was noticed that in all the cases where a moderate or severe bow was present the bow was convex to the ulnar side. This deformity seems to be most difficult to prevent, and may be caused by the use of a collar-and-cuff sling rather than a triangular bandage, as pointed out by Patrick (1946).

Functional Results

Cases classified as a good result were those which had full movement, including full rotation and good muscle power in the arm. Also included in this group are cases where there was a slight degree—i.e., a third or less—of limitation of either supination or pronation or of terminal limitation of movement at the wrist or elbow which did not inconvenience the patient. Where there was a more severe limitation of rotation or limitation of movement in more than one joint, together with any complaint of weakness, the results were classified as either moderate or poor according to the severity. According to these criteria 53 cases were good, 26 moderate, and 11 poor.

Rotatory function of the forearm is considered in more detail. Cases in which operation was necessary are excluded from this section. Cases which developed delayed union are, however, included. This gives 84 cases for analysis. Full rotation was obtained in 37 cases. Rotation was limited in 47 cases. Supination only was limited in 27 cases, but was limited by a third or less in 17 of these. Pronation only was limited in 13 cases but was limited a third or less in 7 of these. Thus full rotation or minimal limitation of either pronation or supination, with no inconvenience to the patient, was seen in 61 of 84 patients considered in this section. More serious limitation of either supination or pronation resulted in 16 cases, and in a further 7 cases both pronation and supination were limited. These results in relation to the sites of fracture were as follows:

Site	*No. of fractures*	
Upper third:		10
Full rotation observed in	3	6
Supination limited by a third or less in	3	
Pronation limited by a third or less in..	0	
Supination more seriously limited in	2	4
Pronation more seriously limited in	2	
Both pronation and supination limited in	0	
Middle third:		33
Full rotation observed in	8	19
Supination limited by a third or less in	8	
Pronation limited by a third or less in..	3	
Supination more seriously limited in	7	14
Pronation more seriously limited in	2	
Both pronation and supination limited in	5	
Lower third:		39
Full rotation observed in	25	35
Supination limited by a third or less in	6	
Pronation limited by a third or less in	4	
Supination more seriously limited in	1	4
Pronation more seriously limited in	2	
Both pronation and supination limited in	1	
Fractures at different levels:		2
Fracture of radius in upper third and ulna in lower third		
Followed by full rotation	1	
Followed by limitation by a half of both pronation and supination	1	

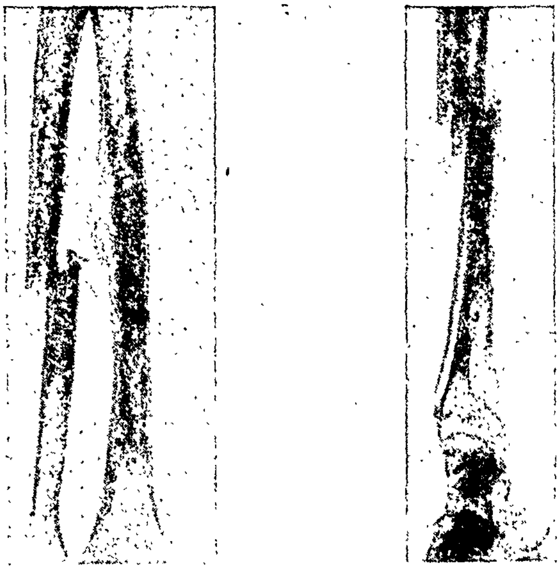


Fig. 9—Fractures of both bones of the forearm.

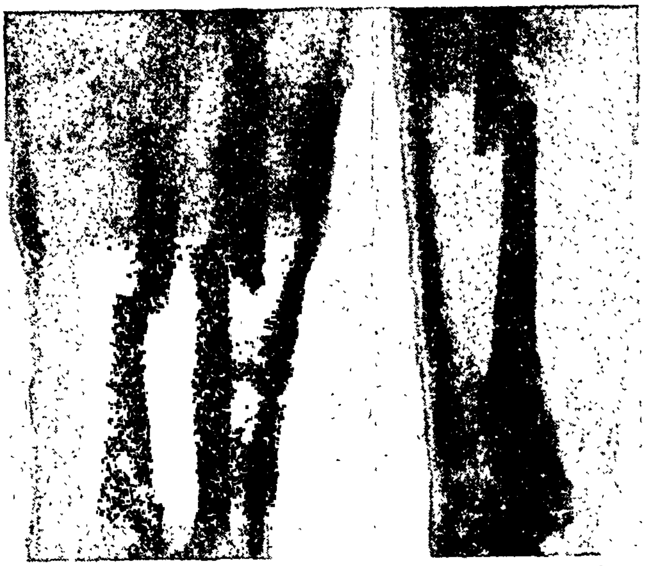

Fig. 10—Same fractures as in fig. 9, showing best position that could be secured by manipulative reduction. Alignment is good. Contact is imperfect.

Thus in 6 out of 10 cases in fractures of the upper third the result as regards rotation was good. In the middle third the good results were 19 out of 33 cases, and in the lower third 35 out of 39. From a superficial examination of these figures it seems that the lower the site of fracture in the forearm bones the better is the prognosis as regards recovery of rotation. Unfortunately no more precise statement can be made than this in view of the relatively small number of patients in each group. What can be said is that in 61 patients out of 84, considered specially from the point of view of recovery of rotation, regained either a full range of movement or nearly so.

Permanent limitation of other movements was a serious feature in but few cases in this series. In 2 patients there remained a terminal limitation of elbow movements, and in 6 others dorsiflexion and palmar flexion of the wrist-joint were limited to a half [illegible] pointed out, this has led to the [illegible] result as moderate or poor according to the severity of the limitation.

Subjective Results

Sixty patients said they were satisfied with their arms and had no complaints; 21 were not satisfied, the common complaints being weakness, aching when the arm became tired, occasionally lack of movement, and rarely deformity. In 9 cases the subjective results were unknown.

Economic Results

A good result is one where the patient returned to the work he was previously doing, and was earning the same wage. A moderate result was one where the patient could not do his previous work but did find some suitable lighter work and his income had not been much affected. A poor result was one where the disability entailed a substantial financial loss. 53 were good, 10 moderate, and 11 poor. In 16 cases the results were unknown.

SUMMARY

92 patients with fractures of both bones of the forearm were treated conservatively and the late results studied.

All were aged more than 21 at the time of the accident.

The anatomical result was excellent in 62% and good in 24%.

The functional result was good in 59% and moderate in 29%.

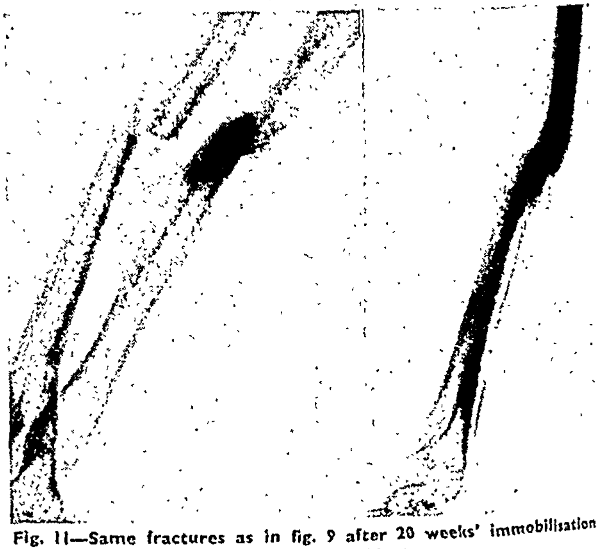

Fig. 11—Same fractures as in fig. 9 after 20 weeks' immobilisation. Non-union is evident.

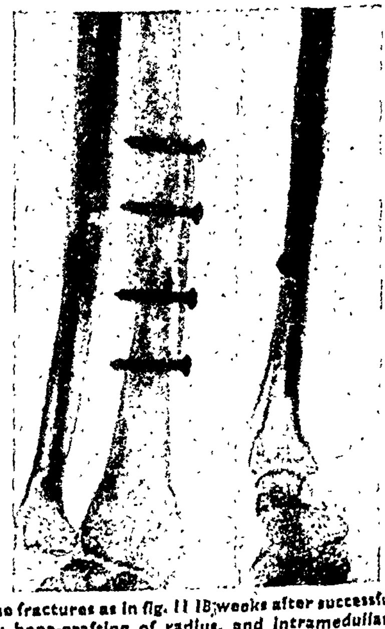

Fig. 12—Same fractures as in fig. 11 18 weeks after successful open reduction, onlay bone-grafting of radius, and intramedullary fixation of ulna. Patient regained two-thirds range of rotation.

The economic result was satisfactory in 70%.

61 patients out of 84 recovered full or almost full rotation.

Non-union occurred in 4 cases, delayed union in 4 cases, and serious mal-union necessitating operation in 2 cases.

We suggest that this method should be retained as a routine treatment for cases where none of the accepted indications for open reduction are present.

We wish to thank Prof. Sir Harry Platt, in whose department this work was undertaken, for much helpful criticism and advice, and Mr. John Charnley for his constant interest.

CYCLOPROPANE ANÆSTHESIA FOR DENTAL EXTRACTION AND OTHER SURGERY IN OUTPATIENTS

REVIEW OF 1000 CASES

J. G. Bourne
M.A., M.B. Camb., D.A.
CONSULTANT ANÆSTHETIST TO ST. THOMAS'S HOSPITAL, LONDON, AND TO SALISBURY HOSPITAL GROUP

Nitrous oxide, alone or with oxygen, has long been the accepted anæsthetic for outpatients. In this paper I criticise this use of nitrous oxide and argue that its low potency, hitherto regarded as an advantage, is in fact both a defect and a danger. Contrary to current belief, a narcotic of high potency might be not only more effective but also safer, and my experience with cyclopropane leads me to think that more nearly than any other it meets the requirements for outpatient work. Of these requirements, safety and simplicity come first, the others being effectiveness, rapid induction and recovery, pleasantness, and low cost.

CYCLOPROPANE

Pinson (1944) described the use of cyclopropane as an anæsthetic for dental extractions in 500 children under the age of twelve: a quarter of the administrations were by students. Disadvantages he found were salivation, and, during recovery, vomiting, which occurred in 21% of cases (Pinson 1945). He concluded that his method was simple and safe, but his technique was somewhat cumbrous and it does not seem to have been widely tried. No reports on the subject seem to have been made since the meeting at the Royal Society of Medicine in 1944 when Marston (1945) advocated cyclopropane for dental extraction in anæmic patients and in those who were difficult or resistant. At the same meeting Gillies (1945) spoke of the administration of cyclopropane to over 800 ambulatory dental patients, and emphasised the value of full oxygenation and "very adequate anæsthesia and muscular relaxation with consequent avoidance of 'smash and grab' surgery." None of them suggested, however, the general adoption of cyclopropane in place of nitrous oxide in outpatient anæsthesia.

The present report is based on 1000 unselected administrations to outpatients, 606 for extraction of teeth and 394 for other minor surgery: 48 were by students under supervision; 134 were by resident anæsthetists; and 91 were by registrar or senior-registrar anæsthetists who were not supervised. 230 patients were under seven and 13 were over seventy years old; the youngest was fourteen months and the oldest eighty-four years. In 20 patients nitrous oxide had failed on a previous occasion and the operation had had to be abandoned.

METHOD

Cyclopropane was given with oxygen from a bag of rather more than 6 litres' capacity. The flow of oxygen and cyclopropane was measured by rotameters, that for cyclopropane being calibrated up to 1600 c.cm. per minute. The gases were conducted to a special angle-piece * (Waters's fitting) containing a sleeve valve. This angle-piece connected the bag to a mask, and the valve enabled the gases to be retained in the bag until the mask had been applied to the patient's face and fitted accurately over the mouth and nose. The valve was then rotated and the patient breathed in and out of the bag. Carbon dioxide could be absorbed by inserting a Waters canister; but, apart from those dental patients who were intubated, in only 1 patient was this made necessary by the length of the operation.

Induction was the same for all patients. The flow of cyclopropane was always 1500 c.cm. per minute and accompanied by an equal flow of oxygen. For induction about 2 litres of each gas was admitted to the bag, and this single dose provided sufficient narcosis for most children and some adults. In the remainder, as soon as inhalation from the bag began, oxygen and cyclopropane were turned on and left flowing at the rate of 1500 c.cm. per minute until the correct depth of anæsthesia was reached. The dose of cyclopropane was thus regulated by duration and not by rate of flow, in the same way that a dose of thiopentone is regulated by quantity not concentration of solution.

In all patients consciousness was lost in from 3 to 6 breaths. At this moment, or a little later, there was often a pause in respiration. Guedel (1940), who employed an identical method of induction, attributed this pause to depression of the respiratory centre, but for the following reasons I regard this interpretation as incorrect:

(1) The pause often occurred at inspiration.

(2) When breathing was resumed it was immediately deeper than before the pause.

(3) In experiments on adult patients not included in this series, carbon dioxide absorption by Waters's to-and-fro method was employed from the start, cyclopropane and oxygen were left running at 1500 c.cm. each per minute, and excess gases were allowed to escape from an expiratory valve. In these patients, as in the others, strong respiration returned immediately after the pause; only after 4–7 min. did respiration show the effects of narcotic depression, which was gradual in onset and slowly progressive. It was further noted that if, when respiration had become considerably depressed, the inhalation was stopped and the patient was allowed to breathe air, not only did full respiration return within two or three minutes but anæsthesia became much lighter as shown by a brisk corneal reflex and other evidence.

During induction and after loss of consciousness motor excitement was evident. Tonic (sometimes followed by clonic) contractions were seen and were occasionally vigorous. In 1 patient, who was an epileptic, they resembled an epileptic attack. This led to the examination by electro-encephalography of 13 patients undergoing this form of anæsthesia, and I am indebted to

---

* From Messrs. A. Charles King Ltd., Devonshire Street, London, W.1.

Dr. T. J. Hutchinson for these examinations and for the following report:

> "At the stage of surgical anæsthesia the record was dominated by high-voltage slow activity at 2 c/sec. These were the appearances one associates normally with that degree of unconsciousness. Normal rhythms became dominant within eighty seconds of terminating the anæsthetic. No E.E.G. evidence of epileptic activity was seen at any time."

After this phase of motor excitement, which usually lasted less than a minute, patients entered surgical anæsthesia and were relaxed. Respiration was normal. This subsidence of excitement was the best sign that the inhalation of cyclopropane could be stopped and the operation started. Another sign was the disappearance of the eyelash reflex. A sign of yet deeper anæsthesia was cessation of oscillating movements of the eyeballs. These last two signs were described by Romberger (1935).

In dental extractions the mouth-prop was inserted after the inhalation of anæsthetic had been stopped, and a pack was then placed in the mouth behind the site of extraction. When difficulty was encountered by the surgeon, as when a tooth was broken, administration of cyclopropane and oxygen was renewed for a few breaths from time to time. When it was obvious that the operation was going to be considerably prolonged, the patient was intubated, the throat was packed off, and anæsthesia was continued with carbon dioxide absorption.

Intubation.—31 adult patients were intubated in the dental chair. After anæsthesia had been induced, as described above, they were given succinylcholine chloride (von Dardel and Thesleff 1951, Bourne et al. 1952), the dose being 0·25 mg. per pound (0·55 mg. per kg.), previously made ready with needle in vein. Inhalation of cyclopropane/oxygen mixture was continued until the succinylcholine had taken effect. Intubation was then performed, the mouth was propped open, the throat was packed with a proprietary vaginal tampon sterilised by autoclaving, and anæsthesia was continued by Waters's to-and-fro method with carbon dioxide absorption. Very little more cyclopropane was needed, even when the operation lasted forty minutes.

RESULTS

Of the whole series of 1000 patients, 21% vomited; but vomiting was never seen during induction or maintenance of anæsthesia, and it occurred only when reflexes had recovered sufficiently to prevent danger. Nausea without vomiting or retching occurred in a further 12% of patients. To prevent nausea and vomiting a small dose of hyoscine by mouth was given to many patients. This experiment, however, was not sufficiently well controlled, and further trials with motion-sickness remedies are being undertaken.

Of patients who had previously been anæsthetised with nitrous oxide and were able to compare their experience of the two methods, 146 expressed preference (usually strong) for cyclopropane while 25 preferred nitrous oxide mainly because after cyclopropane they suffered nausea. Of the 146 patients who preferred cyclopropane several had vomited with cyclopropane but nevertheless preferred it to nitrous oxide. They made remarks like: "I had gas last week and wasn't sick. I was sick today but would still far rather have this." Or "If it was always like this I wouldn't mind coming up any day." Or "Beautiful sensation. Much nicer than gas; lovely." On the other hand, there were a few who said that, though they preferred "going off" clopropane because it was so quick, they would ave nitrous oxide because it did not make it.

the kindness of Prof. F. C. Wilkinson, Sir sev Fry, and Dr. Victor Goldman, over 400 s were anæsthetised for dental tman Dental Hospital, London. At this hospital during the previous twelve months some 8300 patients had been anæsthetised with nitrous oxide/oxygen for dental extraction, and it was therefore possible to compare the two methods. The following conclusions were reached:

(1) As quick induction made up for slight delay in recovery, the length of stay in the dental chair was scarcely any longer with cyclopropane than with nitrous oxide. In one session when cyclopropane was used 15 children were operated upon in forty-five minutes.

(2) With cyclopropane at its worst, operating conditions equalled those with nitrous oxide at its best.

(3) With cyclopropane, bleeding was less than with nitrous oxide.

(4) Even when cyclopropane was administered to more than 40 patients in one day, clearance of the recovery room was almost as quick as when nitrous oxide was used.

(5) The administration of cyclopropane was much easier than that of nitrous oxide.

(6) Vomiting was more frequent after cyclopropane.

(7) The average cost per patient of nitrous oxide was 1*s.* 3*d.* and of cyclopropane 2*s.*

DISCUSSION

Nitrous oxide used with 25% oxygen, as described by Brennan (1952) and supplemented by thiopentone and other narcotics, is regarded by an increasing number of anæsthetists as the anæsthetic of choice for inpatients. In outpatients, however, where effective doses of these supplementary narcotics are precluded by their long action, an attempt is generally made to establish surgical anæsthesia with nitrous oxide and oxygen alone. In all but a few patients nitrous oxide, when used with oxygen at atmospheric concentration, is too weak for this purpose; so, to overcome this difficulty, it is used with concentrations of oxygen that are less—often grossly less—than atmospheric. Thus Clement, who succeeded McKesson at Toledo and in twenty-five years' experience estimated (1951a) his administrations of nitrous oxide/oxygen at 50,000, wrote: "The production of true or surgical anesthesia with N_2O necessitates a restriction of the oxygen intake in the majority of instances" (Clement 1951b); and referring to the "resistant group," he said: "The essentials for success during the induction a[illegible]sure [of gas], the minimum of oxygen in the mixtu[illegible] time element and a disregard of cyanosis" (Clement [illegible]). Kaye (1951), in a study of nitrous oxide anæsth[illegible] in 339 patients, found that "*in . . . 189 cases it was obvious that the third stage of anæsthesia could be reached only by gross restriction of the supply of oxygen.*"

This restriction of oxygen, which permits the highest possible concentration of nitrous oxide, helps in two ways:

(1) The brain is saturated with nitrous oxide as quickly as possible.

(2) Oxygen deprivation itself is employed as a supplementary agent of anæsthesia.

Since, when oxygen is restricted, these two aids are simultaneously present, it is not surprising that opinions differ concerning their relative values. Clement (1951d) said: "The induction of anesthesia with 100 per cent nitrous oxide constitutes a primary saturation. It produces unconsciousness rapidly by a primary saturation of the blood with the anesthetic gas." Macintosh (1952a), on the other hand, has referred to nitrous oxide anæsthesia, when it is brief, as "controlled anoxia." Macintosh and Bannister (1943a) repeated in 50 patients the old experiment of producing anæsthesia sufficient for dental extraction by nasal administration of nitrogen. They found that "anæsthesia" was on the whole satisfactory, and the fact that nitrous oxide was not being used was unknown to dentists and patient. Macintosh (1952b), speaking of dentists' demand for quick recovery following anæsthesia for dental extraction and the means by which it may be achieved, writes :

> "It is virtually impossible to fulfil these requirements with any anæsthetic. . . . There is one condition, however, which gives rise to sudden unconsciousness, leads rapidly to a state approaching death and yet can be reversed almost equally rapidly so that the patient recovers quickly and there are negligible after effects. I refer to acute asphyxia (anoxia)."

But Clement (1951e), also in further statements, admitted that " control of anesthesia is synonymous with control of the oxygen" and " often as little as 1% perceptibly alters the depth of narcosis " (Clement 1951f).

In an interesting annotation in THE LANCET (1868) entitled " The New Anæsthetic (?)," the views of Dr. Richardson, president of the Medical Society of London, were expressed : " Respecting the mode of action of the nitrous oxide Dr. Richardson explained that it was not in the true sense the agent that caused insensibility. . . . In fact, *nitrous oxide is an asphyxiating agent*."

Many anæsthetists have said, and most are aware, that satisfactory anæsthesia is more nearly obtained with nitrous oxide if time is spent over induction. Mushin (1952) has said : " it is a common but erroneous belief that nitrous oxide anæsthesia is a quick method. . . . An average time for induction is 7 to 10 minutes." Kaye (1951) suggested that ten or fifteen minutes were needed, and Clement (1951g) pointed out that time was an important factor with nitrous oxide as with other inhalation agents.

From these and other considerations it would seem that with nitrous oxide there are two different kinds of anæsthesia. The first is seen in the quick " whiff of gas," which probably comprises the majority of outpatient anæsthetics, including those given for the easy extraction of one or two teeth. The anæsthetic and operation are completed in three or four minutes and full consciousness is regained as soon as the patient has taken a few breaths of air. This kind is almost entirely anoxic in character and it could probably be accomplished nearly as well with nitrogen, or any other inert gas, as with nitrous oxide.

The second is the long " gas " lasting ten to twenty minutes or more. Here necessary time is taken for saturation with nitrous oxide, and assistance rendered by deprivation of oxygen can be gradually reduced to a minimum. This kind more nearly approaches true nitrous oxide anæsthesia. Nevertheless, the number of patients in whom oxygen deprivation can be dispensed with altogether is small and consists only of those with low resistance. These are frail people or those rendered frail by severe anoxia during induction by so-called " primary saturation." Between these two kinds of anæsthesia are found every gradation of mixture of both.

Skill in giving a " gas " lies mainly in limiting at all stages the element of oxygen deprivation to the minimum needed for surgical anæsthesia. The field of surgical anæsthesia offered by this method is narrow. On one side is delirium, on the other anoxia in dangerous excess. This may be illustrated by further statements by Clement :

> ". . . nitrous oxide-oxygen anesthesia . . . may be very dangerous in the hands of the novice. The margin of anesthesia . . . is very narrow . . ." (1951h).
>
> ". . . the transition from the light to the deep or even profound plane may occur with bewildering rapidity " (1951i).
>
> " During the induction children respond rapidly to an overdose of nitrous oxide (or lack of oxygen) with manifestations of fourth stage anesthesia and they react equally rapidly to a slight excess of oxygen " (1951j).
>
> " *Alcoholics* usually resist the anesthetic strenuously for a time and then, not infrequently, a sudden *drop into the* dangerous fourth plane may occur with little or no warning " (1951k).

It is small wonder, when the field of surgical anæsthesia is so narrow, that a great deal of training and experience are needed for its safe accomplishment and that anæsthesia is even then not always satisfactory. It is fortunate that the signs of " overdose " are so alarming that practitioners generally err on the side of giving too little. This perhaps explains why the method has been proclaimed safe and why it is possible to produce statistics of very large numbers of administrations with but few deaths. Hewer (1944) stated that a questionary in the United States of America revealed only 2 deaths in 1,161,820 administrations for dental surgery. Marston (1945) referred to 1,271,431 administrations at Guy's Hospital and Dental School without a single fatality. Macintosh and Bannister (1943b), on the other hand, stated :

> " Statistics can be entirely misleading as a guide to the relative safety of the various anæsthetics. Figures may be produced to show that one death has occurred in, say, 50,000 administrations of nitrous oxide, 20,000 of ether, and 10,000 of ethyl chloride. Such figures are valueless because they do not take into consideration such important factors as the skill and experience of the anæsthetist, the state of health of the patient, the nature of the operation, its duration and severity, and they do not show how many times an operation had to be abandoned on account of difficulties in connection with the maintenance of anæsthesia. This last factor is significant, particularly in dental work where every dentist is familiar with the case in which it has been impossible to complete extractions because the length of anæsthesia, or the facilities afforded by *nitrous oxide*, were *inadequate*. Such a case would be classified for statistical purposes as a successful anæsthetic (i.e., not fatal), although it failed completely to enable the operation for which it was given to be performed."

Macintosh (1949), speaking of the danger to a patient with poor heart muscle from the anoxic insult of a " whiff of gas " in the dental chair, stated that he had reports of 5 deaths in as many consecutive months—the coroner in each case being quite satisfied that the anæsthetic had been properly administered. Other evidence suggesting that death or mental disturbance following nitrous oxide anæsthesia are not always so rare is furnished by Courville, who, after describing fatal cases, wrote :

> " While the literature is almost entirely silent on psychosis after nitrous-oxide-oxygen anesthesia, no doubt if the effects were known a goodly number of these unfortunate individuals would be found in the insane asylums of this and other countries " (Courville 1939a).

And, speaking of transitory mental and emotional manifestations, he added :

> " These patients go through an anoxemic episode, present dramatic and alarming symptoms shortly thereafter, but recover more or less promptly, apparently little the worse for the experience. It is very likely that if the facts were known such cases would prove to be more common than is now realized. Doubtless, the anesthetist is glad enough to see the patient safely through the episode, and the story goes unrecorded " (Courville 1939b).

Betten and Courville (1940) stated their belief " that mental disturbances may occur more frequently after nitrous oxide anesthesia than has been generally supposed." " It is likely," they said, " that cerebral and lenticular damage are due to the accompanying asphyxia (anoxic anoxemia) and not to the toxic effects of nitrous oxide itself."

In this paper, however, I am criticising nitrous oxide/oxygen anæsthesia less for its risks than for the unsatisfactory operating conditions it so often produces. It is common knowledge that the standard of anæsthesia for outpatients is far below that now attained for inpatients. A consequence of this unsatisfactory anæsthesia may sometimes be unsuccessful surgery.

Seeking a better solution, some workers have added supplements of one kind or another to the nitrous oxide/oxygen mixture, and have reported degrees of success. To me, however, it seemed that to retain nitrous oxide at all was merely to adhere to tradition; that nitrous oxide, considering how little help it gave in outpatient anæsthesia, occupied too much space in the anæsthetic mixture; and that this space would be occupied to better advantage by oxygen if to oxygen could be added a narcotic that was always effective.

A review of the alternative agents led me to think that cyclopropane might prove to be the most suitable. It could be easily respired at a concentration of 50%, and at this or lower concentration it was capable of producing in all patients anæsthesia of any depth. Its administration, therefore, could be accompanied from the start by oxygen at a concentration greatly in excess of atmospheric. With this method, provided that other respiratory depressants were not given, the field of surgical anæsthesia that lay between too light anæsthesia on the one hand, and respiratory depression on the other, was wide and traversed relatively slowly. In this cyclopropane differed from thiopentone, with which drug respiratory arrest sometimes occurred before surgical anæsthesia was reached. With cyclopropane it is easy to know when the field of surgical anæsthesia has been entered, and in no patient in this series has respiratory depression been encountered.

Hazards with Cyclopropane

1. *Explosion.*—The mixture used was explosive. No flame, therefore, or other source of ignition was allowed near the patient. If there was present even a remote risk of ignition—e.g., when it was intended to use a dental drill—some other method was employed. Risk of explosion was thought to be, for practical purposes, no greater with cyclopropane than with ether, ethyl chloride, or 'Vinesthene,' given with nitrous oxide or oxygen.

2. *Arrhythmias.*—Guedel (1940), in a study of more than 8000 administrations of cyclopropane in inpatients, used a method of induction which was identical with the one employed here and followed induction by yet heavier doses of cyclopropane. He concluded that "cardiac arrhythmias . . . although they must be respected, need not be feared."

Griffith (1951) reported a series of 20,000 unselected hospital inpatients to whom he had given cyclopropane with only 1 death under anæsthesia, the cause of which was not stated. He thought that, in spite of pulse irregularities which it sometimes initiated, cyclopropane was the anæsthetic of choice for patients with serious heart-disease.

Waters and Gillespie (1944), in a study of 47 deaths occurring during anæsthesia in 44,894 patients, ascribed 24 in whole or in part to anæsthesia. 5 of these patients died, they said, in a manner suggestive of abrupt cardiac failure during anæsthesia with cyclopropane. Later in their report they suggested other possible causes of death in 3 of these 5. In the remaining 2 they stated that death was undoubtedly due to primary cardiac failure. It is, however, noteworthy that in 1 of these 2 patients there was mild obstruction to respiration, and that in the other death occurred in deep anæsthesia and at necropsy coronary sclerosis was found. These authors concluded: "In our hands cyclopropane has proved no more dangerous than other agents."

It is impossible as yet to say how great may be the hazard of primary cardiac failure in outpatients who are unpremedicated and usually fearful. Questions equally unanswerable are: What is the true mortality with nitrous oxide? How often is mental impairment produced by the anoxia which accompanies it? Is the risk with cyclopropane greater or is it less than with nitrous oxide?

SUMMARY AND CONCLUSIONS

Though nitrous oxide has been widely used for many years, it may have been responsible for a higher mortality and morbidity than is generally supposed.

Apart from this, it does not fully meet the requirements of outpatient anæsthesia. Its administration is neither simple nor highly effective. Induction and, to a less extent, recovery are rapid only with the short "whiff of gas" when the main agent of anæsthesia is not nitrous oxide but anoxia. Induction is not always pleasant; unconsciousness during operation is sometimes incomplete; and nausea and baneful symptoms from anoxia not infrequently attend recovery when anæsthesia is prolonged. Its low cost is offset by the expense of unsuccessful surgery, which sometimes results from bad operating conditions.

Provided cyclopropane is given by someone who is sufficiently instructed and experienced to give an anæsthetic safely, it is both more effective and also safer than nitrous oxide. But the anæsthetist has always to bear in mind the following facts:

(1) Cyclopropane is explosive.

(2) An equal or greater flow of oxygen must always accompany its flow.

(3) With cyclopropane, as with any other anæsthetic, a clear airway must always be maintained.

(4) If any difficulty arises 100% oxygen must at once be administered, if necessary under pressure by compressing the breathing-bag.

Unlike the use of nitrous oxide, the use of cyclopropane is simple and easily learnt. Induction is very rapid and recovery sufficiently so for all practical purposes. While induction is usually considered pleasant and unconsciousness is always complete, recovery is frequently marred by nausea or vomiting. The cost is not high.

Whereas it is now an accepted principle of inpatient anæsthesia that anoxia is harmful and to be avoided, in outpatient practice anoxia is still deliberately employed as an agent of anæsthesia. Outpatient anæsthesia will not be improved so long as nitrous oxide continues to be used.

I am grateful to Mr. J. D. Robson and Mr. P. Shemilt, of Salisbury, on whose patients much of this work was done; to Dr. Victor Goldman for inviting me to work at the Eastman Dental Hospital; and to Dr. J. Hendrie, anæsthetic registrar, for his kind assistance.

PHLEBOTHROMBOSIS AND NERVOUS STRESS

S. B. STOKER
F.R.C.S.E.
FORMERLY SURGEON, DEWSBURY INFIRMARY, YORKS

IN recent years considerable attention has been directed to phlebothrombosis and pulmonary embolism, and much evidence about their causal factors has accumulated; but the application of treatment developed from these studies has not consistently altered the incidence of fatal embolism.

MASSIVE THROMBOSIS

"Massive thrombosis" here denotes the bland non-infective propagated clot whose liberation causes pulmonary embolism. The incidence of this condition, cited by Jorpes (1946), has varied in different clinics. Before the advent of early postoperative exercises and ambulation, fatal postoperative pulmonary embolism occurred in 0·1–0·5% of cases. Early postoperative exercise has reduced the incidence by more than half in many series of cases; but not in all. The mortality of thrombo-embolism, when it occurs, is over 20%.

Massive thrombosis was originally thought to be a complication of surgery. Later it was shown that it can occur in an even higher proportion of medical inpatients, but in comparing medical and surgical cases it must be recognised that the pathological material concerned is likely to be very different and the ætiological factors not exactly the same. The medical wards will often have a higher proportion of cases with circulatory defects, whereas the surgical patients are likely to be subjected to pecial nervous stresses. Pathological studies of necropsy material have shown that in a large proportion of bodies blood-clots are found in the veins of the legs and feet. Hunter et al. (1945) found, in 169 necropsies, such clots in 17·9% of patients who had been exercised up to forty-eight hours before death, and in 53·1% of patients who had not been so exercised. Hunter et al. (1941) noted that the age of the clot corresponded to the length of time the patient had been in bed.

Raeburn (1951), as a result of histological studies on veins obtained at necropsy, believes that venous thrombosis in the leg is a chronic additive process. The theory now generally held is that the small primary venous thrombus, which is so often present, merely needs the stagnation of the blood-stream by confinement to bed to allow rapid propagation of the clot. The stagnation of venous blood due to confinement to bed has become the all-important factor of massive thrombosis:

"The common denominator in phlebothrombosis and pulmonary embolism is *confinement to bed*. The reason for going to bed is unimportant" (Hunter et al. 1945).

If the immobilisation of a patient in bed is the main requirement for producing massive thrombosis, the incidence of this condition should be the same outside as inside hospital; but this does not appear to be so. In 1944–49 in the town of Ossett, with 11,000 inhabitants over school age, there were notified only three cases of fatal pulmonary embolism. No non-fatal case was recognised during this period. A fourth patient with pulmonary embolism was admitted to hospital, where she died. Only one of these patients had been confined to bed with illness immediately before death.

The confinements to bed in Ossett in 1944–49 may be divided into (1) those of the normal nightly retirement and (2) those of a few days or more due to illness. Three of these thrombosis cases were in the first category, and only one in the second. The incidence in the first category is about 1 in 8,000,000 adult retirements, and in the d much less than 1 in 18,000 adult illnesses. The figures for the second category are obtained from the practices of four out of the five general practitioners and by a conservative estimate of the cases attended by the remaining doctor, whose records are no longer available. Almost all of these cases will have been confined to bed for at least two days. Chronic sick cases, although adding their quota of 1 (the only case in the second category) to the thrombosis death returns, have not been included in the figures, owing to the difficulty of obtaining the necessary data and because this will compensate for some of the cases being outside the district under discussion. In both categories it is obvious that there is a great difference between home and hospital conditions, and that mere confinement to bed is no more than an added factor to something also of importance which probably initiates the formation of the clot.

Even though we do not dispute the importance of venous stagnation in the legs, we are bound to look for some difference between treatment at home and treatment in hospital. Some light may be thrown on this subject by the observation that sometimes a clot is found suddenly during emotional stress.

ILLUSTRATIVE CASE-RECORD

A woman, aged 24, who had lost a considerable amount of weight in the last few months, consulted her doctor about it and about lack of energy, but continued in active employment as a rag-sorter. She had no cough or other symptom.

On examination she was small and slim, and had obviously lost weight, but apart from anæmia no other physical abnormality was found. She was agitated and worried because her sister had died of phthisis a year previously and she had a brother in a sanatorium with the same disease.

A specimen of her urine was delivered a few days later by her mother, to whom was explained the necessity for hospital investigation. The patient was informed of the arrangements the same evening. This produced great agitation, and she expressed the fear of what the X rays might reveal. Next day she complained to her family of pain in both legs: this persisted for two days. She was fully ambulant during each day. On the third day after the arrangements had been made for her admission to hospital, her doctor was called and found her suffering from severe chest symptoms which suggested pulmonary embolism. She died soon after admission to hospital.

Necropsy showed that death was due to a pulmonary embolus, there was ante-mortem clot in the left external iliac vein, and the lungs were filled with miliary tubercles. The leg veins were not examined.

In this case factors other than emotion might have added their effects to the result; but there was a definite nervous stress associated with the initiating of the clotting process. It seems likely that many cases of acute coronary occlusion occurring after emotional stress are due to a similar process. Thrombosis of piles and varicose veins may also sometimes be associated with nervous stress. An elderly patient attended by me developed thrombosis of a varicose vein immediately after finding that her house had been burgled.

AUTONOMIC NERVOUS SYSTEM AND BLOOD-CLOTTING TIME

Ample evidence has been published to demonstrate the effect of autonomic-nerve stimulation on blood-clotting time (B.C.T.). Cannon et al. (1914) obtained consistent reduction in B.C.T. in cats by injecting adrenaline and by producing nervous excitement in them. With larger doses of adrenaline the B.C.T. was first retarded and then considerably reduced. Similar results have been obtained by other workers. Mills et al. (1928) demonstrated that the rate of clumping of platelets was related to the speed of clotting of shed blood, and that adrenaline injections accelerated both processes.

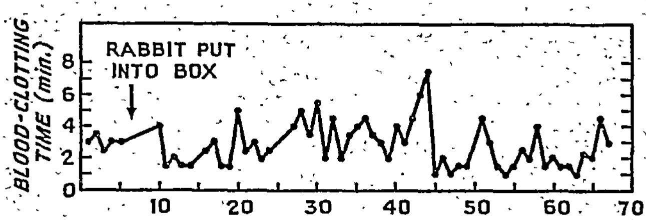

Fig. 1—Changes produced by nervous excitement in the clotting-time of venous blood in a rabbit placed in a box with its head protruding.

In experiments on rabbits, dogs, and man, in which the B.C.T. was followed minute by minute with a multiple coagulometer (Stoker 1945) I repeatedly recorded distinct changes apparently due to nervous excitement. In one such experiment (fig. 1) the excitation consisted of putting a struggling rabbit into a box from which its head protruded. Fig. 2 shows the result of an intravenous injection of adrenaline on the B.C.T. of a rabbit. Consistent results were obtained in six such experiments in which adrenaline 0·025–0·05 mg. per kg. of body-weight was used. In other experiments, unconnected with this group, the few minutes of very short B.C.T. were sufficient so to occlude the vein that it was useless for further withdrawal of blood.

In the course of examining the B.C.T. by means of capillary punctures in a young medical student a venepuncture was made. The student fainted, and the resulting changes in B.C.T. are shown in fig. 3. This graph is very similar in appearance to those obtained by Cannon et al. (1914) when small doses of adrenaline were injected. A similar result in another student coincided with an acute headache which began in the middle of the experiment. As the headache disappeared the B.C.T. returned to normal.

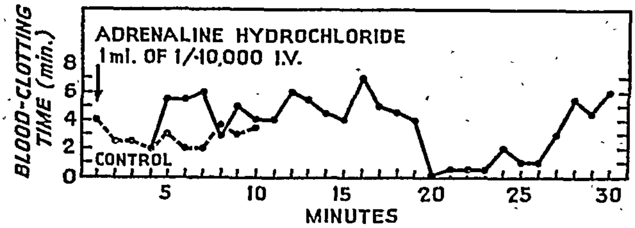

Fig. 2—Changes produced by intravenous adrenaline in the clotting-time of venous blood in a rabbit.

DISCUSSION

In recent years little reliability has been placed on blood-coagulation tests in relation to thrombosis; yet this is essentially a blood-clotting process. It may, of course, be argued that the B.C.T., within limits, will not determine the formation of a clot, and this view seems reasonable provided that there does not exist the nidus upon which a clot can be rapidly formed. The nidus, a preformed clot, such as pathological investigations suggest, is often present in adult veins. If the blood-stream is slowed and if, at the same time, the coagulability of the blood is greatly increased, there is likelihood of a propagated clot. This increase in blood coagulability may be much greater than published B.C.T. results indicate. On three occasions I have seen this reduced to a fraction of a second—twice in experiments on animals and once on the hospital operating-table. In each case, when the veins were cut, the blood mushroomed out to consolidate in a raised mass before it could flatten out on to the surrounding tissue. Reference to the accompanying figures will show that this state of hypercoagulability may last only a few minutes. In other words, it may be an acute process which may be entirely missed by occasional blood-tests.

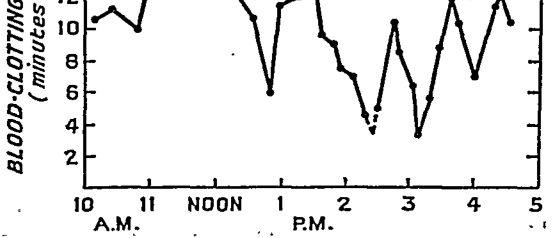

Fig. 3—Changes produced by a faint in the clotting-time of capillary blood in a medical student.

That confinement to bed can be no more than a contributing factor in massive thrombosis is seen by the statistics of patients treated at home and in hospital. The blood stagnation due to recumbency is common to both and, in fact, will be even greater in home cases than in those receiving prophylactic treatment in hospital. The great variation in the hospital statistics is significant and suggests that confinement to bed is only a part of the story.

Clinical experience shows that intravascular clotting can be initiated by nervous excitement or stress. Experimental evidence shows that rapid blood coagulability may be produced by nervous stress as well as by operatively handling the body. We must accept the numerous pathological reports that thrombi, as potential starting-points of massive thrombosis, are present in a large proportion of adults at least after a brief period recumbent in bed, and the view that slowing of the venous stream in the legs is an important factor in this disease. The patient in hospital will have all these factors at work. Which is lacking in the patient at home in his own bed? Nervous stress is surely one such factor.

Most hospital workers do not appreciate the many causes of nervous stress in patients. Mere admission to an unknown hospital ward may cause nervous tension, and the work of Hunter et al. (1941) suggests that this may be a dangerous time. The age of their clots corresponded to the duration of recumbency. Small matters, in the view of the hospital staff, such as shyness in asking for a bedpan, the fear that it will not be available when needed, and the self-consciousness in using it in close proximity to others, may be a severe nervous strain. Many doctors will have heard these views voiced. In larger matters, such as waiting in dread for the operation, the solution should be easy. Apart from the question of thrombosis such points might well receive more attention from a purely humanitarian point of view.

Hadfield (1950) states:

> “The rate of venous flow in the lower limbs of a healthy young adult can be diminished to a surprising but never to a dangerous degree by simple confinement to bed. It falls to an appreciably lower level in those with an ageing *myocardium*, to a lower level still if the vigour of respiration is diminished, and, if to these handicaps were added general muscular immobility, *the stage is set for peripheral venous thrombosis*.”

The stage is at present receiving considerable attention. The prevention of the actor, nervous stress, from playing his part must be a matter of clinical *trial*. Sedation begun before admission to hospital and continued in doses sufficient to meet emergencies might produce good results.

SUMMARY

The incidence of phlebothrombosis and pulmonary embolism in a small provincial town is discussed.

Experimental evidence is reviewed to show that nervous stress may be a deciding factor in producing massive intravenous thrombosis.

It is suggested that the apparent increased risk of massive thrombosis in hospital is due to nervous stress, and that such nervous stress is less in patients treated at home.

I wish to thank Drs. F. Cane, J. S. Coad, W. D. Mitton, and A. M. Ramsay for making available their sick-attendance records; Dr. W. G. Evans, M.O.H. of the district, for supplying the figures of the death returns; and Prof. D. Burns in whose department of physiology in Newcastle upon Tyne the illustrating experiments were made.

HUMAN ECTOPIC FASCIOLIASIS

B. N. CATCHPOLE
M.B. Manc., F.R.C.S.
SURGICAL TUTOR IN THE UNIVERSITY OF MANCHESTER

D. SNOW
M.B. Manc., M.R.C.P.
EGISTRAR, DEPARTMENT OF CARDIOLOGY, MANCHESTER ROYAL INFIRMARY

THE liver fluke, *Fasciola hepatica*, is a common parasite of sheep and to a lesser extent of cattle and hogs, causing the disease known as " liver rot." Although of world-wide distribution, it is most common in Cuba and has there become of importance owing to the infection of man.

It might be expected that human infestation would correspond to that of animals, but in fact fascioliasis rarely affects man. Burgi (1936) collected 186 cases of human fascioliasis, and well over 200 cases have now been published. In this country 14 cases have been recorded, the first in 1852. There seems to be little doubt, however, that many more examples of infestation are encountered during operations on the biliary tract without being recorded.

Normally the adult fluke inhabits the bile-ducts, its eggs being excreted with the fæces. Rarely, however, the parasite may be found in various ectopic situations—e.g., blood-vessels, subcutaneous tissues, and brain. Burgi (1936) reviewed 16 cases of ectopic fascioliasis published up to 1933. Since then 8 more cases have been published, making a total of 24, of which only 1 has apparently occurred in this country—in a sailor who had been abroad for many years and had therefore probably been infected outside this country.

CASE-RECORD

A hotel housekeeper, aged 30, first attended the outpatient department at the Manchester Royal Infirmary on June 28, 1950, with a tender swelling in her abdominal wall. A week previously she had had some tenderness in her right iliac fossa, followed next day by a swelling there. Two days later the swelling had moved to the right lumbar region and become bigger, and thence to the right rib margin. The patient's general health remained good.

On examination a non-tender subcutaneous mass $1\frac{1}{2}$ in. in diameter was found overlying the ninth costal cartilage. It was thought to be due to low-grade inflammation, and short-wave diathermy was prescribed. A week later there was no apparent change in the swelling, and it was decided to admit the patient for its removal as a possible fibrosarcoma.

On admission on July 16 the patient said that the overlying skin had recently become discoloured. The swelling had become attached to the skin, there being a hard nodular superficial part with a softer and less defined deeper portion tethered to the external oblique aponeurosis.

Biopsy.—The mass was excised and found to consist of yellowish fatty tissue containing pus-filled necrotic areas, from one of which a small parasite measuring 4×2 mm. was expressed. This was kindly identified by Dr. F. O'Rourke, of the Liverpool School of Tropical Medicine, as an immature specimen of *Fasciola hepatica*.

Investigations.—Numerous unsuccessful attempts were made to recover ova from the duodenum and fæces. Eosinophilia was, however, found, varying between 744 and 978 per c.mm.

Treatment and progress.—Emetine hydrochloride gr. $\frac{1}{2}$ daily was given for eighteen days, while the patient was under the care of Prof. Robert Platt. Immediately afterwards the eosinophil-count was 792 per c.mm. Two weeks later it was 336 per c.mm., and in six months it was back to normal at 82 per c.mm. (for this latter count we are indebted to Dr. G. Anderson, of Bedford General Hospital, the patient having by that time left Manchester). It seems reasonable to assume that the patient no longer harboured any parasites.

Despite inquiry, particularly by Dr. Metcalfe Brown, medical officer of health for Manchester, no source of the infection was traced.

DISCUSSION

Location of Parasite

It was formerly believed that after ingestion of the cercariæ by the definitive host, the immature flukes passed up the common bile-duct to reach their final habitat; but it has now been shown (Krull and Jackson 1943) that the young flukes migrate through the gut wall into the peritoneal cavity, penetrating the liver capsule and substance to reach the bile-ducts. This observation helps to explain the location of the parasite in certain ectopic cases.

The finding of parasites in ectopic sites has led some observers (Braun and Seifert 1925, Bugge 1928) to postulate a venous route for migration to the liver and thence to various sites throughout the body. Faust (1939) supports this view, and it appears to be the most reasonable explanation in some cases.

In the 24 ectopic cases published, excluding the present case, the sites were as follows: portal vein 1, peripheral veins 2, stomach 1, appendix abscess 2, peritoneal granuloma 1, cerebrum 1, urine 1, subcutaneous tissue 14, and unknown 1. Of the infections involving the subcutaneous tissues 9 were in the right hypochondrium.

Thus it seems likely, as Burgi (1936) has suggested, that the parasite may reach the subcutaneous tissue directly by a relatively small deviation from its usual route to the liver. The finding of parasites in the stomach, peritoneum, and appendix can be explained in a similar way.

Blood spread seems likely to be the mode of distribution of more distantly located ectopic parasites, though Giesker and Frey (cited by Burgi 1936) claim that their patient with a parasite in the sole of the foot was directly infected by cercariæ penetrating the skin.

Migration of Parasite

This was a notable feature of the present case, the swelling first appearing near the right inguinal ligament and migrating to the right costal margin in some seven days. This phenomenon has been previously seen. Malherbe (cited by Burgi 1936) describes a case in which a painful swelling near the left scapula moved downwards about 10–15 cm. in fourteen days, when a young fluke was removed. In the case reported by Chatron and Rondeau du Noyer (cited by Burgi 1936) a swelling as big as a hazel nut to the right of the umbilicus decreased in size, and later a new swelling appeared higher up, which contained a 4 mm. fluke.

Immaturity of Fluke

The immaturity of the fluke in the present case accords with the findings in other cases of ectopic fascioliasis, and seems to be due to the lack of essential environmental factors necessary for full maturation which are found only in the liver and bile-ducts.

Source of Infection

This is of interest because of the great rarity of human cases in this country. Contaminated watercress or other vegetation is the usual source of ova. Our patient could not remember having eaten any possibly contaminated food. She had never been further abroad than Jersey, which she visited in the previous year, and for the four months preceding her attendance at hospital she had not left the Manchester area.

Within fairly wide limits it may be possible to fix the time at which infestation occurred, because it takes only 4–6 days after ingestion for the fluke to traverse the peritoneal cavity. Thus infestation may be reasonably presumed to have taken place not less than a week, and probably not more than a month, before the appearance of the swelling.

We must therefore conclude that infestation was contracted in this area, but the source and mode are unknown. The medical officer of health for Manchester kindly informed us that no other cases had been reported in the area.

We are grateful to Prof. A. M. Boyd for permission to report this case; to Dr. F. O'Rourke, of the Liverpool School of Tropical Medicine; and to Dr. Metcalfe Brown, medical officer of health for Manchester.

HÆMOPHILIA-LIKE SYNDROME FROM ANTICOAGULANTS AFFECTING THE PRODUCTION OF THROMBOPLASTIN

I. S. Collins
M.B. Sydney, M.R.C.P.
MEDICAL REGISTRAR

D. G. Ferriman
D.M. Oxfd, M.R.C.P.
PHYSICIAN

NORTH MIDDLESEX HOSPITAL, LONDON

Some syndromes resembling hæmophilia are due to circulating heparin-like antithrombins, and others to an anticoagulant apparently inhibiting the production of plasma-thromboplastin. Eighteen of the latter type of case have been published, of which the earliest was that of Lozner et al. (1940). We report here a further such case.

CASE-RECORD

A man, aged 73, with advanced widespread rheumatoid arthritis for ten years, had enlarged axillary glands, and cutaneous nodules over the right elbow and hip. His liver and spleen were not enlarged. He had never had any gold therapy. The bleeding disorder, which started in January, 1951, was manifested by extensive subcutaneous and intramuscular hæmorrhages (including two into the root of the tongue, embarrassing respiration), hæmatemeses, melæna, and hæmaturia. He died of massive hæmorrhages in November, 1951.

Treatment with hæmatinics, transfusions, antihæmophilic globulin, and adrenocorticotropic hormone (A.C.T.H.) 100 mg. the first day and 40 mg. daily for six more days had no effect on the underlying disorder.

Investigations.—The erythrocyte-sedimentation rate was moderately raised. White-cell counts were within normal limits. The plasma-protein level and liver-function and Congo-red tests were normal. The Wassermann reaction was negative. Serum-mucoproteins were somewhat increased. Splenin B was found in considerable amount, and splenin A was virtually absent (Greene et al. 1952). Clotting-times ranged between 10 and 60 minutes (Lee-White). Bleeding-times, platelet-counts, capillary fragility, serum-calcium, and plasma-fibrinogen were all normal. The blood-group was A Rh-negative. The presence of an anticoagulant was repeatedly demonstrated by the prolongation of clotting-time of normal blood on addition of the patient's blood—e.g., 25 minutes, compared with 13 minutes in the control.

The anticoagulant was investigated by one of us (I. S. C.). Prothrombin and thrombin times were normal, as were the results of titration with protamine sulphate (Allen et al. 1949). The serum-prothrombin time was short: 29 sec. compared with 100 sec. following clotting of normal blood (a rather weak thromboplastin was used in this experiment). Dr. R. G. Macfarlane and Dr. R. Biggs, using special techniques, showed that our anticoagulant inhibited the formation of plasma-thromboplastin but had no effect on this substance once it had been formed. Excess of a potent platelet-factor suspension supplied by Professor van Creveld (van Creveld and Paulssen 1951, 1952), restored to normal the clotting-time and serum-prothrombin time of mixtures of normal blood with our anticoagulant (table I). The suspension contained no thromboplastin, as was confirmed by its failure to make any significant alteration in the clotting-time of recalcified normal plasma: 2 min. 23 sec. compared with 2 min. 35 sec. in the control. Comparable experiments with antihæmophilic globulin failed, the preparation seeming to have anticoagulant properties of its own in excess. Activity of the anticoagulant was apparent in a dilution of 1 part of patient's plasma to 3 of normal plasma but not in a dilution of 1 : 10. The anticoagulant retained its activity after four months at −20°C, and was active after three days at room-temperature, but deteriorated somewhat after seven days.

TABLE I—NEUTRALISATION OF ANTICOAGULANT BY PLATELET FACTOR

Normal blood	+	+	+
Anticoagulant	−	+	+
Platelet factor	−	−	+
Clotting-time (min.)	17	23	11
Serum-prothrombin time (sec.) ..	62	15	120

It was not destroyed by heating to 65°C for 5 minutes. The residue after dialysis retained anticoagulant activity. Chemical and electrophoretic fractionations were made by Dr. R. A. Kekwick. Studies of these fractions appeared to show activity in both the beta and gamma globulins but not in the albumin and alpha-globulins.

Necropsy findings.—There were large recent ecchymoses of the chest wall and neck, old and recent bilateral hæmothoraces with adhesions, and altered blood in the gut. The liver showed siderosis. The sternal, costal, vertebral, and femoral bone-marrow was uniformly erythroblastic. The spleen was enlarged to almost twice the normal size, very soft and autolytic, and siderosis was increased.

Histological examination confirmed these findings and showed amyloid change in the axillary lymph-glands but none in the liver. No discovery of note was made in the pituitary, suprarenal, or thyroid glands. There were general cardiovascular changes commensurate with the patient's age, and the urinary tract showed appearances associated with prostatectomy for adenomatous prostate.

DISCUSSION

The outstanding features in the present case and in eighteen similar cases previously published are compared in table II.

Ætiology

The patients fall into three main groups:

(1) The first consists of eight apparently typical hæmophiliacs. In these the anticoagulant has usually been found

after multiple transfusions or the giving of antihæmophilic globulin. The anticoagulant disappeared after treatment was stopped in one of the cases reported by Frommeyer et al. (1950). Precipitins to antihæmophilic globulin have been reported in two cases by Craddock and Lawrence (1947) and in five cases by Frommeyer et al. (1950). It has been suggested that antihæmophilic globulin acts as a foreign protein in hæmophiliacs, leading to the appearance of antibodies.

(2) The second group is made up of four women whose anticoagulants appeared shortly after a pregnancy. Dreskin and Rosenthal (1950) collected seven previously published cases of pseudohæmophilia in women, in four of whom the disorder appeared shortly after pregnancy. It has been suggested that the development of the anticoagulant is an auto-immunisation phenomenon.

(3) Six of the seven remaining patients were elderly males, in five of whom the hæmorrhagic disorder appeared during some other illness. The natures of these illnesses were consistent with the suggestion that the anticoagulants appeared in response to some disturbance of immunity mechanisms.

The anticoagulants have always been found in the globulins, particularly the gamma-globulins obtained on chemical and electrophoretic fractionation of the plasma (table II). This is consistent with the suggestion that these anticoagulants are antibodies.

Action of Anticoagulants

Prothrombin-times were normal in all these cases, excluding any abnormality or inhibition of prothrombin, thrombin, fibrinogen, or the various accelerators of the conversion of prothrombin to thrombin, but not of thromboplastin, because the excess of tissue thromboplastin added in doing this test would probably obscure such an effect. Serum-calcium and plasma-fibrinogen levels were normal where estimated. Heparin-like antithrombins have been excluded by further tests in all but one of these cases (Singer et al. 1950).

It follows that the anticoagulants interfere with either the action of thromboplastin or its formation from platelet factor and antihæmophilic globulin. This has been confirmed by the finding of impaired prothrombin consumption, as shown by short serum-prothrombin times in all the cases where these have been estimated. Attempts to determine which of these three substances are primarily affected by the anticoagulants have not been entirely successful. The results of certain types of experiment devised for this purpose have been capable of more than one interpretation. Certain investigations and tentative conclusions, however, can be recorded. Investigations have failed to reveal any satisfactory evidence that the anticoagulants antagonise plasma-thromboplastin, and most observers consider such an action unlikely. The most hopeful approach to distinguishing between effects on platelet factor and those on antihæmophilic globulin has been to show neutralisation of the anticoagulant by an excess of one or other factor. This has been successful with platelet factor (Lamy et al. 1946, Conley et al. 1950, Singer et al. 1950, and ourselves). It should be noted that the patient reported by Lamy et al. belonged to the hæmophilic group. These results cannot be regarded as conclusive, because they may be due to a mass-action effect. Shinowara (1951) has shown that platelet factor is an extremely potent lipoprotein—like tissue thromboplastin (Chargaff et al. 1944) and probably plasma-thromboplastin—a few microgrammes possessing physiological activity. Platelet-counts have been estimated in most cases and found normal, and the platelets from one patient restored to normal the clotting-time of platelet-freed normal plasma (Dieter et al. 1949). Neutralisation experiments with antihæmophilic globulin have been unsuccessful, but this may be due to a technical cause. It should be remembered that precipitins to antihæmophilic globulins have been demonstrated in several cases from the hæmophilic group (see above).

To summarise: these anticoagulants probably interfere with the formation of plasma-thromboplastin, though how they do so is unknown.

Identity of Anticoagulants

These anticoagulants have largely similar physical and chemical properties (table II). Such differences as are reported may have technical explanations. The anticoagulants are mostly non-dialysable and are comparatively resistant to storage and heating. They have been found in the globulin and, where investigated, the gamma-globulin fractions. Their similarities and the possibly common ætiological mechanism suggest a related if not identical group of substances. Tocantins (1943) found an anticoagulant in normal plasmas. It is conceivable that the underlying disorders provoke the appearance of some such anticoagulant in abnormal titre. Investigations into the action of the anticoagulant throw no conclusive light upon the matter but suggest a possible difference between those arising in hæmophiliacs and those arising in non-hæmophilic persons.

Clinical Features

The disorder closely resembles hæmophilia, but the hæmorrhages favour somewhat different sites. Massive subcutaneous and intramuscular hæmorrhages are common. Hæmorrhages into the root of the tongue, causing embarrassment of respiration, are notable features. Hæmorrhages into joints are less common. Gastro-intestinal hæmorrhages and hæmaturia are common. An important difference lies in the response to transfusions. These correct the lack of antihæmophilic globulin in hæmophilia; clotting-times are improved; and bleeding ceases. They do not affect the anticoagulant; clotting-times are largely unaffected; and hæmorrhage may continue.

Many of the cases have been reported a few months after the appearance of the anticoagulant; hence information about the possible duration of the illnesses is limited. The available information is collected in table II.

Treatment

Treatment is unsatisfactory. Nothing is known which affects the underlying disorder. Cortisone was tried without avail by Singer et al. (1950) and A.C.T.H. by ourselves. All that can be done is to correct the anæmia with transfusion. The development of a thromboplastin which could be used safely by the intravenous route would be helpful. The use of placental blood (Pons and de Torregrosa 1952) may be a step in this direction, because its efficacy is quite possibly due to a high content of thromboplastin.

Frommeyer et al. (1950) found an anticoagulant had appeared in no less than 5 out of 27 cases of hæmophilia. He advised against the use of antihæmophilic globulin, and recommended that transfusions should be used only sparingly, in hæmophilia, to avoid this complication.

SUMMARY

In a man, aged 73, with rheumatoid arthritis, a condition resembling hæmophilia developed, due to a circulating anticoagulant.

Eighteen previously published similar cases are reviewed.

The anticoagulants are thought to interfere with the formation of plasma-thromboplastin.

Their appearance may be in response to some disturbance of the mechanism of immunisation.

Physical and chemical similarities between the anticoagulants are noted. It is possible, though perhaps improbable, that they are a related group of substances.

We wish to thank our house-physician, Dr. M. H. Aitken, for her help; Dr. J. F. Heggie and Dr. A. B. Anderson for much laboratory investigation and facilities; Dr. R. G. Macfarlane and Dr. R. Biggs for a specialised investigation; Professor van Creveld for the supply of platelet factor; Miss J. Vaughan-Morgan, B.SC., for the splenin investigation; Dr. J. F. Bach for the supply of A.C.T.H.; and Dr. C. J. C. Britton, Dr. Raymond Greene, and Dr. Macfarlane for encouragement and advice. We are particularly indebted to Dr. R. A. Kekwick, of the Lister Institute, for the lengthy fractionations he kindly undertook for us.

CAROTENÆMIA

R. M. S. McCONAGHEY
M.D. Edin.
GENERAL PRACTITIONER

An excess of carotene in the blood-plasma is produced by the ingestion of large quantities of foods rich in carotene, such as carrots, pumpkins, and papaw. Consumption of these foods for six months or more causes yellow discoloration of the mucosæ and skin, especially the horny layers of the palms and soles. The sclera are never affected, and the urine is not darker than normal.

The condition was first observed by von Noorden (1907), who regarded it as a diabetic manifestation. Moro (1908) noted that normal infants developed a similar yellow pigmentation when carrots were added to their diet. van den Bergh and Snapper (1914) showed that lipochrome pigments were circulating in the blood of those diabetic patients who exhibited an orange pigmentation.

Single cases have been reported from various parts of the world (Head and Johnson 1921, McGill 1922, Niehaus 1924, Stoner 1928, Stannus 1929, Potts 1929, Levin and Silvers 1931, Curtis and Kleinschmidt 1932, Rutledge 1933, Gandy 1935, Sequeira 1936, Wood and Agnor 1941, Schafer and Slentz 1949). Anderson and Soley (1938) collected and reported on thirteen cases from California; Josephs (1944) searched the records of Johns Hopkins Hospital and found six cases and reported a further case himself. In this country Almond and Logan (1942) reported four cases, in one of which the pigmentation was passed to a child through the mother's milk. These cases occurred during the war 1939-45 and seemed to be a direct consequence of Lord Woolton's appeal to the civilian population to eat carrots, which were then plentiful. The present two cases were encountered during the autumn of 1951.

Carotenæmia is said to be more likely to develop in diabetes mellitus, where it is probably a result of the diet rather than the disease, and in myxœdema, where there is some evidence that the carotene antagonises thyroxine (Anderson and Soley 1938).

CAROTENE

Carotene is the yellow colouring matter in the lipochrome of carrots, spinach, palm oil, and nettles. It is a highly concentrated hydrocarbon, $C_{40}H_{56}$, which exists in three forms—alpha, beta, and gamma. All three forms are precursors of vitamin A, but the alpha form produces twice as much as the other two, and is the one present in the largest quantities in natural products. Lycopene is the isomer of carotene and the colouring matter of tomatoes, rose hips, and bitter-sweet berries but does not form vitamin A. Carotene is the principal lipochrome in human serum. It is always associated with its hydroxyl derivative or xanthophyll.

Lutein is the xanthophyll of alpha carotene and is the lipochrome in egg yolk and green leaves. The normal daily requirement of carotene is 3 mg. or 5000 units. There is 2000 units in $^1/_4$ lb. of carrots.

DIFFERENTIAL DIAGNOSIS

The importance of carotenæmia lies in its recognition. When the offending articles of diet are withheld, the yellow pigmentation slowly clears. The four cases reported by Almond and Logan (1942) had been previously diagnosed as gall-stones, jaundice, pernicious anæmia, and hæmolytic anæmia. White sclerotics are the key to the diagnosis.

A simple test for lipochrome in serum consists in shaking up equal parts of the serum, alcohol, and petroleum ether, and allowing them to settle. The alcohol precipitates the protein and absorbs the bilirubin, and the lipochromes are absorbed by the petroleum ether.

CASE-RECORDS

Case 1.—A married woman, aged 42, with one child aged 8 years, had been depressed, bad tempered, and tired for three weeks. For some years she had been catering, first in a youth hostel and later in a guest-house. She described herself as a "liverish" person who could not eat fats. She was plump and had voluntarily tried to cut down on starches. About eight years ago she read that carrots were good for catarrh, and gradually began to consume them in increasing quantities. During this summer she had been living almost exclusively on them. Her daily consumption had been $1^1/_2$–2 lb. of raw carrots daily. Several weeks before she sought medical advice she had noticed that her hands and feet were yellow, and was afraid to mention it to anyone. Five days ago her husband noticed it and assumed that she had jaundice.

On examination the whole of her skin was tinted yellow, and there was yellowish staining on her buccal cavity. Her palms and soles were particularly yellow, the discoloration being greatest on the callosities. Her sclerotics were white, and her urine pale straw-coloured without albumin or sugar. Her blood-pressure was 150/90 mm. Hg and heart sounds were normal. She had slight tenderness in her epigastrium and complained of flatulence. Her fæces were of normal colour. She could see well in the dark.

Investigations.—The serum-carotene level was 500 mg. per 100 ml. (normal 240 mg. per 100 ml.). The serum-vitamin-A level was 51 mg. per 100 ml. (normal 70–160 mg. per 100 ml.). A blood-count showed Hb 78%, red cells 4,900,000 per c.mm., and white cells 7500 per c.mm.

Treatment and Progress.—When the carrots were discontinued, her yellow discoloration gradually faded in six weeks.

Case 2.—A married woman, aged 40, with children aged 13 and 3 years, complained of lassitude and nervousness. During the last five months of her first pregnancy she had eaten large quantities of carrots. Three years ago, during her second pregnancy, she had a persistent craving for carrots, and now, for the past six months or more, she had a return of the craving and had eaten them to the extent of 1 lb. a day. She noticed yellowness of her hands but had thought that it was sunburn wearing off.

On examination she was plump and over-weight (11 st.) and had generalised yellow pigmentation of the skin, which was quite bright on her palms and soles. Her sclerotics were white. Her blood-pressure was 130/80 mm. Hg. No other signs of disease were observed.

Investigations.—The serum-carotene level was 330 mg. per 100 ml.; serum-vitamin-A level 27·5 mg. per 100 ml.; blood-cholesterol level 200 mg. per 100 ml.; Hb 70%, red cells 4,400,000 per c.mm., and white cells 12,000 per c.mm.

Outcome.—On being assured that the condition was not serious, the patient declared she would rather be yellow with carrots than pale and carrotless, and refused to discontinue her diet.

DISCUSSION

These two cases have several points in common. Both patients were rather plump women approaching their menopause; both complained of lethargy and nervousness; both had slight hypochromic anæmia; and both had an insatiable desire for carrots, the second patient so much that she refused to give them up.

I have met carotenæmia once before, when it was again in a middle-aged woman, whose dietetic indiscretion was papaw. This was in India during the war, and I was unable to investigate it.

I wish to thank Dr. G. Stewart Smith, pathologist to the Royal Devon and Exeter Hospital, for help and advice in investigating these cases.

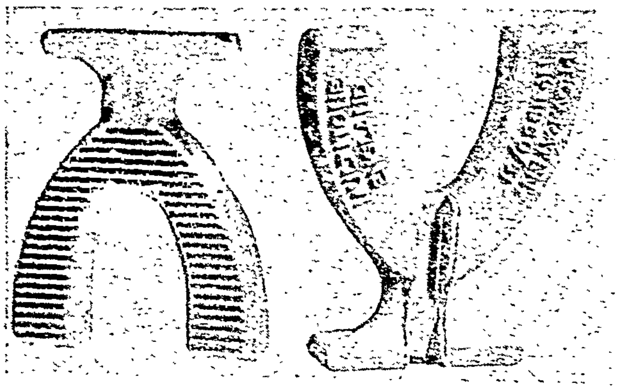
New Inventions

MOUTH GAG FOR ELECTROCONVULSION THERAPY

It has been customary to use transverse indiarubber gags for electroconvulsion therapy and similar procedures. These, however, distort the mouth, impede respirations, and place the strain of the clenched jaws on the front and premolar teeth, with the result that these are often loosened or broken. Fractures of the mandible have also been reported. Relaxants are seldom advisable to the extent that convulsion is entirely eliminated, and even with relaxants the spasm of the jaws remains strong.

The gag illustrated was designed to engage all the patient's teeth. It is made of toughened indiarubber and is easily sterilisable. It does not distort the mouth, and the tongue is left free though protected against protrusion between the teeth; respiration is not impeded by the gag; and the channel in the upper surface will accommodate an endotracheal tube if required. With this gag the strain of the muscle spasm is placed mainly on the molars, which are better adapted to stand this strain, and whose position relieves the weakest part of the mandible of strain. A stem and crosspiece facilitate insertion and removal.



The gag has been in regular use for some months and is greatly preferred to other forms. The spreading of the area of bite leads to less damage to the gag as well as to the patient. The gag is manufactured by Messrs. Multitone, 223–227, St. John St., Clerkenwell, London, E.C.1, from whom it may be obtained.

Brain Tumors of Childhood

H. M. CUNEO, M.D., assistant clinical professor of neurological surgery, University of Southern California; C. W. RAND, M.D., clinical professor of neurological surgery, University of Southern California. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 224. 42*s.*

THIS useful and concise account of brain tumours of childhood is a further addition to the American Lecture Series and is based on 83 verified cases treated in the Children's Hospital in Los Angeles within ten years. As the authors indicate, the diagnosis is often made late because the possibility of brain tumour being responsible for the symptoms is not sufficiently borne in mind. The warning that young children do not complain of failing vision until they are almost blind is timely, and it is clear that the routine use of the ophthalmoscope in clinical examination would bring some cases under observation much earlier.

The book is arranged according to tumour type, and each chapter begins with a summary of current opinion, with adequate references. Not every neurosurgeon will agree with the conclusion that all children suspected of a cerebellar tumour should have preliminary ventriculography; there are many cases in which the diagnosis is not in doubt and in these circumstances air studies may only upset an already ill child.

The production and illustrations are first-class. Two clinical photographs express most poignantly the problem and the challenge in this subject.

History of Neurological Surgery

Editor: A. EARL WALKER, M.D., professor of neurological surgery, Johns Hopkins University. London: Baillière, Tindall, & Cox. 1951. Pp. 583. 91*s.* 6*d.*

THESE lectures, delivered by members of the Johns Hopkins University, have been welded into a historical survey of the progress of neurological surgery. Much of it is a bald citation of facts which in themselves make an enthralling story of conquest, and reconquest, in an unusually difficult field. We all know how ancient is the operation of trepanning, but it is strange to realise how widely it was practised over the world, and that in some forgotten way infection was avoided. Air ventriculography was accidentally demonstrated in 1913, but its possibilities were not perceived, and it was left for Dandy to rediscover and develop it in 1918. Neurological surgery began in England, but its great progress in America was very largely due to the influence of one man—Harvey Cushing—who insisted that the surgeon undertaking to operate on the nervous system must also be a neurologist. The neurosurgeon no longer operates at the behest, and according to the directions, of the physician, but on his own initiative; and since a frightening power of altering personality lies in his hands, it is right that he should be a man of high intellectual attainments and culture. But neurological surgery, like all surgery, is a mechanical art; its scope, now still expanding, will be restricted when the more subtle secrets of physiology ultimately become clear to us.

Il Cuore Artificiale

E. TOSATTI. Milan: Istituto Sieroterapico Milanese S. Belfanti. 1951. Pp. 151. 700 Lire.

THE great progress in cardiac surgery has brought into prominence international attempts to perfect a pump-oxygenator capable of taking over temporarily the work of the heart and lungs. This little book, in Italian, is the first general review of the subject. The author, an active worker in this field, discusses the problem from both theoretical and practical standpoints, and presents the principal solutions offered up till the end of 1951. The various machines described are well illustrated by actual photographs, and numerous diagrams make clear the techniques employed in using them. At this early stage in the development of these machines no one is completely satisfactory; but the problem is a real one, and this book is most helpful in providing a basis for judging the merits of these and future attempts.

The Temporomandibular Joint

BERNARD G. SARNAT, M.D., M.S., D.D.S., F.A.C.S., professor and head of department of oral and maxillofacial surgery, College of Medicine and Dentistry, University of Illinois. Springfield, Ill. Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1951. Pp. 148. 35*s.*

THIS monograph is founded on various lectures on anatomical, pathological, and clinical aspects of the joint given by various members of the faculty of the University of Illinois.

The internal pterygoid muscle is not regarded as playing any part in side-to-side movements of the mandible as has been widely taught in the past. A discussion of the relation of the mandibular condyle and the growth of the neck of the condyle to the growth of the jaw as a whole is followed by a section on pathological conditions of the jaw: the conclusion that Costen's concept of a syndrome connected with mandibular overclosure should be abandoned will find general agreement in this country where it has never had much currency. The section on those abnormal conditions of the joint which result in pain and clicking is unfortunately rather short, and by no means everyone who deals with this type of case will agree that restoration of correct occlusion of the teeth, where this is faulty, will cure all but a few cases. Most of the clicking jaws seen in this country are in young women in whom there is usually a history of anxiety at the time when the habit started. In many cases clicking occurs not at the beginning of the opening movement but later in opening the mouth, and it is hard to see how malocclusion can account for clicking at this juncture. Lack of muscular balance, which eventually becomes a habit, may often account for the condition. It is a pity that there is not fuller discussion of this subject rather than an analysis of three cases treated by a particular method.

The book is illustrated by good photographs and diagrams.

The Foot (4th ed. London: Baillière, Tindall, & Cox, 1952. Pp. 466. 25*s.*).—Mr. Norman C. Lake still finds that the foot presents him with puzzles; but in every edition of this useful little work he is able to announce that a few more of them have been solved. The revised and informative text is supplemented with good illustrations, 30 of them new.

Progress in Clinical Medicine (2nd ed. London: J. & A. Churchill. 1952. Pp. 426. 27*s.* 6*d.*).—The editors, Dr. Raymond Daley and Dr. Henry Miller, have carefully continued their policy of including only those advances which promise to be of permanent value; and they have firmly excluded, as of no great interest to the general physician, the latest news from the highly specialised fronts of medicine. New chapters have been added on industrial medicine and physical methods of treatment in psychiatry; and sections are now included on cerebral angiography, electrolyte and water balance, cortisone and A.C.T.H., hypersplenism, toxoplasmosis, electrocardiography, parkinsonism, and the newer antibiotics. The editors and their fellow contributors have done wonders in very little room, and they have produced an excellent book.

Emergencies in Medical Practice (3rd ed. London: E. & S. Livingstone, 1952. Pp. 587. 32*s.* 6*d.*).—Dr. C. Allan Birch and his team of twenty-one contributors have had to decide, as usual, which emergencies shall rank as medical; and in this new edition they have decided to include *ileus*, acute dilatation of the stomach, and tetanus as being surgical emergencies with medical aspects. Otherwise, the book has been improved by revision and pruning, and embellished with some new illustrations in colour. Colour is an uncertain ally, however. The plate illustrating the colouring of mushrooms is discredited by the fever-pink hand supporting them; and the coloured photographs of blood-transfusion technique are woolly and too small. The coloured photographs of ocular conditions are good, however, and most of the other illustrations are clear and helpful. The book remains the friend on whom the doctor with a patient in a tight place can call for help; but perhaps it is even better read beforehand.

THE LANCET

LONDON: SATURDAY, OCT. 11, 1952

Future of the Occupational Health Services

SINCE the Dale Committee on the Industrial Health Services produced its disappointingly modest proposals nearly two years ago, there has been a lull on this front. Even the interdepartmental advisory committee which the Dale report recommended has not yet been formed. Recently, however, some guns got into action at Margate, where the Trades Union Congress and the Royal Sanitary Institute held their annual meetings. In the T.U.C. the general council accepted a resolution by Dr. BRUCE CARDEW calling on the Government to set up "a comprehensive occupational health service to be welded into the National Health Service"—though it "wanted to be careful that such welding does not produce integration for the sake of administrative ease."[1] This reservation was an echo of BERTRAND RUSSELL's warning (quoted by Dr. R. S. F. SCHILLING[2] at the other Margate meeting) of the "administrative fallacy in which the tidiness of the plan is regarded as a model of order—an end in itself—and of men in control . . . who forget what human beings are like and try to fit men to systems, rather than systems to men." Dr. CARDEW seriously overstated his case when he said that, while the National Health Service was the best in the world, when "once a man left his home for his office, shipyard, factory, or mine the provisions for his health became perhaps the worst in the world." And Mr. ALFRED ROBERTS went a little too far when he spoke of the "appalling lack of knowledge of occupational hazards and diseases among general practitioners." But at the Royal Sanitary Institute's meeting the statements were more measured.

Prof. I. G. DAVIES, medical officer of health for Leeds, in a thoughtful and well-balanced paper[3] on the future organisation of the occupational health services, drew attention to the danger of an artificial separation between treatment at work and at home. Any proposed industrial health arrangements must not, he said, have the effect of creating fresh divisions among the medical profession: rather should they aim at drawing the existing sections closer together, and, where possible, making a common service. There is urgent need, in his opinion, for development of a preventive health service for all places of work, including those beyond the scope of the Factories Act, and this could be done by fusing the duties of the three kinds of medical officers who are already operating statutory services of the kind required—namely, the medical inspectors of factories and mines, the appointed factory doctors, and the medical officers of health. One difficulty here, he thought, would be the administrative gulf (almost an abyss) which lies between officers appointed by central and by local government departments. But "it is worthy of serious consideration that, as a first step, legislative and administrative means be found to fuse the statutory health officers already engaged in preventive health services into one preventive health unit enforcing and maintaining health standards." Dr. DAVIES claimed that this step would solve the essential and immediate problem for the small factories. For the large industrial organisations, and for single industrial units employing large numbers, special arrangements may be necessary; but even there, he held, the main bias of the service must essentially be preventive in character, leaving treatment to the N.H.S. He recognises that this may make too sharp a distinction between preventive and curative medicine; but preventive medicine, he said, requires the enforcement and maintenance of standards arrived at after research and investigation and then embodied in law and administrative procedure. He thinks that a new medical inspectorate at three levels—central, regional, and local—should be created to work under the authority of statute and in close association with the general inspectorate, both centrally and locally. The present medical inspectors of the Ministry of Labour would provide the regional level, and it would be one of their functions to establish medical liaison with the administrative medical officer of the regional hospital board and through him with the hospital and specialist services. At the local level it is suggested that the medical officer of health and his staff, assisted by the appointed factory doctor, should be responsible, in association with the local factory inspectorate, for detailed enforcement and maintenance of health standards and for medical examinations. Dr. DAVIES believes that such an arrangement could be made now at very little additional cost and without disturbance of medical man-power.

This approach by a medical officer of health to the problem of occupational health is refreshing and original, and seems to us more promising than that of the Glasgow city council, which is endeavouring to solve its local problem directly by setting up an industrial medical service staffed by full-time medical officers of its own. It is natural, and in a way logical, that medical officers of health should wish to take over industrial health, but in urging their case they have sometimes tended to play down the importance of occupational medicine and to ignore the experience and pioneering work of the Factory Department and others in the field. The Ministry of Health, too, has not been altogether guiltless in this respect, and its attitude has probably contributed to the resistance of the Ministry of Labour to the proposal that the health departments should control all health affairs. This conflict came into the open at the Caxton Hall conference in 1943, when Mr. ERNEST BEVIN and Mr. ERNEST BROWN each put forward the claims of his own Ministry, and it may be partly responsible for inactivity and lack of progress in occupational health matters.

Addressing the Association of Industrial Medical Officers six months ago, Dr. H. WYERS[4] said that industrial medicine must come to terms with the medical officer of health sooner or later, and the sooner the better: "his passion for administration should be exploited, but his pre-occupation with community health tempered." In Dr. WYERS's view, preventive and curative medicine should be united. Certainly

[1] *Manchester Guardian*, Sept. 3, 1952.

[2] *J. R. sanit. Inst.* 1952, 72, 534.

[3] *Ibid.* p. 528.

1. *Trans. Ass. industr. med. Offrs*, 1952, 2, 64.

Dr. Davies's idea of the rôle of the medical officer of health should be more acceptable to the other interested parties than that put forward by some previous spokesmen of the public-health service, who have not recognised that occupational health is a field in which they have little or no experience. Dr. Davies appreciates the objection to his scheme that it would entail delegation of central functions to local authorities, but he thinks that a medical officer of health could be seconded for medical inspectorial functions to the factory inspectorate without the actual responsibility being placed in the hands of the local authorities. It would be essential to such an arrangement that the medical officer of health should work in close association within the administrative framework of the local factory inspectorate, as indeed he does now to some extent. In this way, Dr. Davies believes, liaison with the N.H.S. could be secured—at regional level with the specialist and hospital services, and at local level with general practitioners through the medical officer of health.

In a paper which we published a few weeks ago [5] Dr. Peter Nash urged that occupational-hygiene laboratories should be set up in various parts of the country. This attractive idea cannot be said to be new, for it has been put forward from time to time by various individuals and organisations over the past fifteen years or so. Nor is the concept of the "health engineer" really a novelty in Britain, for the engineering and chemical branch of the Factory Department has long been carrying out the procedures he describes. It is true that there is no special laboratory for the use of the Factory Department; but work is done by the Government Chemist and the National Physical Laboratory, and the Mines Department is fortunate in that routine and emergency tests of environmental conditions are made in the Safety in Mines Research Laboratories in Sheffield. At the same time we cordially agree that there is need for extension of the facilities and staff in the Factory Department and we welcome Dr. Nash's paper as a basis for discussion. He usefully drew attention to the precedent set by the laboratories of the Public Health Laboratory Service, administered by the Medical Research Council: there are 18 special or reference laboratories and a further 49 constituent laboratories. For work on occupational hygiene, fewer centres would be needed, and possibly some of the public-health laboratories could be used or adapted. As Dr. Nash says, there is a strong case for the centres to become part of the Factory Department of the Ministry of Labour, and another possibility is that industry itself should be encouraged to set up such centres. The need for them is shown by the fact that his own laboratory at the London School of Hygiene and Tropical Medicine is getting more requests for help than it can deal with.

Surely the time has come for the interested Ministries to get together and hammer out an acceptable scheme for the better organisation of the occupational health services to cover all occupations? New legislation will be needed and it is inevitable that one or more Ministries or departments should surrender some of its sovereignty, though we must always bear in mind that a tidy administrative plan is not necessarily the best. Until this is done, little or no progress can be expected.

---

[5] *Lancet*, Sept. 6, 1952, p. 478.

Cervical Osteo-arthritis and the Spinal Cord

The association of cervical osteo-arthritis or cervical spondylosis with disorder of the spinal cord has only lately been recognised as a fairly common occurrence. Spillane and Lloyd [1] [2] have described 21 cases, and Russell Brain, Northfield, and Wilkinson [3] 38; and as a result of their work the condition should be diagnosed more readily. Men are affected more often than women, the commonest age of onset being the early fifties. Disability usually starts with stiffness and weakness of the legs, which gradually increase, and may be associated with paræsthesiæ and clumsiness in the hands and, less commonly, with pain in the arms. Only rarely does the patient complain of pain in the neck. The symptoms slowly become worse over the course of two to three years, and then not uncommonly become stationary, without further deterioration, for a considerable time. There is a variable degree of spastic paraparesis, and some patients have atrophy of the shoulder-girdle muscles, often with fasciculation, while others have only a slight generalised weakness. The arm reflexes vary; it is perhaps commonest to find that all the arm-jerks are pathologically brisk, but in some cases the biceps jerks are diminished, and there is inversion of the radial reflexes. Sensory impairment is less constant than motor disability, but there may be diminution of position sense in the hands, giving a clumsiness to the finger movements, and, less frequently, a loss of position and vibration sense in the feet. Cutaneous sensory impairment was found in three-quarters of the patients in the London Hospital series [3]; it was commoner in the arms than in the legs, but it was seldom more than a slight loss. There may be surprisingly little to find on clinical examination of the neck; passive movements are usually free and painless, but occasionally there may be some limitation of movement. In the majority of patients lumbar puncture gives a normal response in the Queckenstedt test, and the cerebrospinal fluid shows no abnormality; but in a few cases there may be a slow rise on jugular compression, The protein content of the C.S.F. was raised to between 70 and 80 mg. per 100 ml. in 5 of Spillane's patients, and it was over 50 mg. in 10 patients in the second series, the highest value being 160 mg. per 100 ml.

X-ray examination of the cervical spine is the most helpful investigation; but at times the results may be difficult to interpret, for osteo-arthritic changes, unassociated with clinical symptoms or signs, are not uncommon in middle age. In cases where there is uncertainty about the diagnosis, myelography is necessary. The most important abnormalities to be found on straight X-ray examination are narrowing of one or more of the intervertebral disc spaces; osteophytes on the anterior and posterior aspects of the vertebral bodies (the latter being particularly significant); changes in the articular surfaces of the neurocentral joints; and projection of osteophytes into the intervertebral foramina (best shown in oblique projections). If myelography is needed, it should be carried out with the patient prone, 3–5 ml. of opaque oil being injected. The significant findings are one or more transverse breaks in the oil column opposite disc spaces; the delay in the passage of oil across these breaks often lasts several minutes when the patient is tilted head downwards at an angle of 70°. The lateral view may show indentation of the oil column opposite one or more disc spaces in the cervical spine. In the control myelograms that SPILLANE performed on patients in similar age-groups who were suffering from other forms of paraplegia, these characteristic features were absent. Obviously the clinical syndrome of cervical osteo-arthritis with cord changes resembles certain intrinsic diseases of the spinal cord—particularly motor-neurone disease, subacute combined degeneration, and disseminated sclerosis. So, when these conditions have atypical features, X-ray examination of the cervical spine, and if necessary myelography, should be carried out.

---

[1] Spillane, J. D., Lloyd, G. H. T. *Lancet*, 1951, ii, 653.
[2] Spillane, J. D., Lloyd, G. H. T. *Brain*, 1952, 75, 177.
[3] Brain, W. R., Northfield, D., Wilkinson, M. *Ibid*, p. 187.

BEDFORD, BOSANQUET, and RITCHIE RUSSELL[4] have described the post-mortem findings in one such case. There were well-marked ridges in the disc spaces between C5 and 6 and C6 and 7, "which expanded laterally into two discrete osteophytic protrusions." An atrophic 7th cervical root was stretched over one of these spurs. The ridges in the disc spaces were formed by disc protrusions covered by bony outgrowths from the edges of the adjacent vertebræ. The spinal theca was adherent to the posterior longitudinal ligament, and it had been held firmly enough against the bone for the ridges to have caused indentations in it. The cervical enlargement of the cord was shrunken, but there was no kinking of the cord, and the theca on the posterior surface lay quite loosely over the shrunken cord. Sections of the cord showed degeneration of both grey and white matter in the C5 and 6 segments; many nerve cells ere destroyed, and there was gliosis and ascending nd descending degeneration in the long tracts. Similar changes in the spine were recorded in 6 of the London Hospital cases, and the nerve-roots of the affected segments were bound up in adhesions between their dural sheaths and the edges of the intervertebral foramina.

Injuries of the cervical spine may give rise to sudden protrusion of a disc with damage to the cord; or, more rarely, progressive protrusion of a cervical disc may gradually compress the cord, giving the clinical picture of an extradural tumour; but the condition associated with cervical osteo-arthritis is of a different kind. It is probable that the intervertebral discs undergo a degeneration which excites an osteophytic reaction in the bodies of adjacent vertebræ. The damage to the cord is due, in part at least, to pressure of the transverse ridges against the front of the spinal theca and to narrowing of the anteroposterior diameter of the spinal cord. Moreover, the tethering of the nerve-roots in the intervertebral foramina reduces the normal mobility of the cord and makes it more liable to injury during movements of the cervical spine. The adhesions may also interfere with the blood-supply to the cord.

If this is the way in which the cord is damaged, conservative treatment should consist in immobilisation of the cervical spine, preferably with halter extension of the neck followed by a plastic collar or other device to prevent constant cervical movements. In a number of patients, particularly in the early stages of disability, this treatment will stop the progress of the disease and definite improvement may take place. Surgical treatment has also been tried, with variable results. Removal of the hard bony ridges is technically very difficult and there is a danger of injury to the spinal cord. The usual operation has been a full laminectomy at the affected level, followed by "unroofing" of the intervertebral foramina, opening of the dura, and division of the denticulate ligament. This procedure is designed to give greater mobility to the spinal cord and to relieve pressure on the nerve-roots. In the London Hospital series 21 patients had this operation: there was definite improvement in 4 cases, a lesser degree in 10 others, and no change in the condition of another 4; and there were 2 postoperative deaths. The younger patients and those whose symptoms had been present for only a short time did best; these are the people who also responded well to immobilisation, which seems to be the method of treatment favoured by the evidence so far.

Withdrawal of Teaching

MEMORY is the most essential of the servants of reason, and the least reliable. Knowing this, every good teacher uses devices to make his teaching memorable. He points his argument with wit, illustrates it with examples, develops imitable mannerisms, sets his class chanting mnemonics and rhymes, excels in coaxing the timid or galvanising the slack, cultivates understatement or overstatement, or shies things about. But whatever method his temperament drives him to adopt, his aim is to ballast the free-floating fact with affect and image. The simpler the student and the more complex the subject, the greater the need of such ballast.

The Ministry of Health have the ultimate responsibility for teaching many complex subjects, both to the population at large and to informed or semi-informed groups within it. For this vast educational undertaking they have for years been developing the use of documentary films. The value of those made for the general public is now well established: the decline in diphtheria mortality, a steady rise in standards of handling food, and the growing public interest in child care owe much to such films. In the territory of medicine and nursing the Ministry have been equally enterprising in passing round essential information quickly, economically, and memorably. Three recent examples may be described to illustrate the exceptional value of this method of teaching.

All physicians and surgeons are aware of the importance, in the prevention of cross-infection, of capable and conscientious nursing technique. Yet it is a formidable task to teach a girl fresh from school, often with no background of science classes, to think imaginatively about the transfer of infective organisms from one patient to another, and to govern her conduct accordingly. To instruct her in unfamiliar principles in classroom and ward is one thing; to get her to build them into her professional conscience—so that she suffers unbearable guilt if she fails to apply them—is quite another. The remark of one nurse, "Asepsis is something you don't bother about when sister isn't there," suggests that ordinary teaching methods do not always succeed in creating an equally powerful but interior autocrat.

---

[4] Bedford, P. D., Bosanquet, F. D., Russell, W. R. *Lancet*, July 12, 1952, p. 55.

The documentary film, *Prevention of Cross-infection: Gastro-enteritis in Infancy*, made for the Ministry of Health by the Central Office of Information (C.O.I.), and written and directed by Margaret S. Thompson, shows the results of failure in technique in terms of a healthy baby brought close to death; the emotional significance of the film is thus strong. The nurse responsible is guilty of only one small breakdown in an otherwise faultless barrier technique. The path taken by the infected material is made visible in the form of black markings, transferred, from the napkin of a child with gastro-enteritis, first to the hands of the nurse, thence to the lid of the napkin bucket, thence back to her newly washed hands, thence to her apron, thence to a borrowed pencil, and so to the hands of the lender of the pencil, and finally to the teat of a bottle from which a healthy child is to take a feed. The last shot of the critically ill baby could not easily be forgotten.

This film serves the double purpose of showing every step in correct barrier nursing as well as the outcome of the one false step. A single showing might well do as much as a dozen lectures to establish the preventive outlook; and moreover it can be shown to a large group of nurses at a time.

One exacting duty of the Ministry is to get our hospitals to profit from each other's experience. Many improvements never get beyond the walls of the hospital which makes them, simply because they are never heard of elsewhere.

The film *There's a Way*, directed by Gerry Bryant, is the engrossing story of a hospital in need of a reablement unit. The doctor in charge of the small overworked physical-medicine department, the Scottish surgeon who supports him, the various members of the hospital management committee, the almoner, and all the other hospital characters, come plausibly to life. The patients are alive already, and most of the time kicking, walking, running, twisting, catching, or otherwise exercising disabled limbs. A plan to build a full-scale reablement department has been turned down by the regional hospital board on grounds of expense, and the film shows how an effective department was improvised at very little cost in an old Army hut. First the hospital management committee has to be won over; and then six months pass before the R.H.B. sanctions the scheme. At last, with old materials from the hospital storeroom, the enthusiasts convert half the hut into a gymnasium, and fit part of the rest up with physiotherapy cubicles and an office for the almoner. The gym class is in full swing within a month; but the hospital still lacks an occupational-therapy department. An industrialist on the management committee contributes a lathe, and other equipment is given by the townspeople. The work of this department is illustrated cleverly from the case-histories of genuine patients, and the whole film is a trustworthy picture of the way a reablement unit can be contrived with very little outlay and an addition of only four members to the staff. The story is told with the skill and veracity which distinguished the work of the Crown Film Unit.

This film is addressed to hospital medical and administrative staff, physiotherapists, almoners, and other social workers. A third group of films addressed purely to a medical audience is concerned with curable cancer.

These substantial documentaries, six in all, each run for 30–40 minutes; and each shows such a range of cases of cancer in a given site as could scarcely be assembled in any single hospital, and would certainly not be seen by a family doctor in a lifetime of practice. The film dealing with cancer of the skin, for instance, shows rodent ulcers at every stage, from the first unbroken nodule to the ulcer which has destroyed an entire face. Moreover, it shows what treatment can nowadays achieve: how the malignant process can be stopped by radiotherapy, even when structural damage is extreme; how extensive are the areas of malignant infiltration which can be successfully excised; and what the plastic surgeon and the maker of prostheses between them can achieve in the way of repairs. Other types of skin cancer, including the dangerous melanoma, are also shown, appropriate warnings being given in sound-track and captions. A film on breast cancer follows the same plan, the emphasis here being on the survival-rate of 80% for cases treated early. A third film, on cancer of the larynx, shows how radiotherapy, or, failing that, surgery, can completely deliver the patient of his disease and restore him to normal life with very little disability. An interesting sequence here shows the training—sometimes very successful—of laryngectomised patients in the use of the œsophageal voice. There are also films on cancer of the lip and tongue, the rectum, and the cervix and uterus.

These films have an extraordinary impact, not only because they state memorably the results of neglect but also because they give such a vivid idea of what can be done. Receiving both impressions together, the watching doctor is bound to experience a strengthening of his sense of responsibility.

All these films would formerly have been seen by very large audiences. Until early this year the C.O.I.'s mobile film units, serving not only the Ministry of Health but all the Ministries, were able to show educational films wherever they were wanted: hospitals, medical and nursing schools, local authorities, and other responsible bodies only had to write and ask for a booking. In April, however, when the mobile units and—more unfortunately still—the Crown Film Unit were disbanded, as a minor Government economy, this first-class piece of educational work was abruptly cut down. The film projectors of the mobile units are to be distributed, but even if some of them find their way into hospitals among 2800 hospitals they will not, of course, go very far. When a hospital now wishes to show its medical or nursing staff an educational film it usually has to begin by borrowing a projector for the purpose; and moreover, it now has to pay for the hire of films which formerly were shown free of charge. The charges compare favourably with commercial rates, but the misfortune is that there should be charges at all. As a result, less use is being made of the Central Film Library of outstanding educational films, and the skilled and experienced staff who made many of these films have been scattered.

It seems essential that the mobile units should somehow be replaced: and surely one of the voluntary bodies interested in medical education will think this a worthy object? But even if existing films can again be put into circulation, it is unlikely that the beautifully economical system by which the mobile units served all the Ministries could be repeated. This miserable little economy has meant a saving of about £50,000 a year on the mobile units—not a very noticeable figure in the national budget—and of about £180,000 on the service as a whole, including the cost of running the Crown Film Unit. The loss cannot be measured in money at all.

USES OF PUNISHMENT

THE effects of a generous and regular allowance of punishments—expensive ones, too—are conveniently apparent in the case of the old lag. It is a waste of time and money to go on punishing someone in the same old way for something he is going to go on doing. As Dr. Minski points out in our correspondence columns this week, the recidivist looks on society as his enemy, and every fresh term of imprisonment confirms this impression. Why should he put himself out for an institution which dislikes him so much?

A similar frame of mind, as parents know to their cost, can sometimes develop in children. Prof. Richard Ellis, in his Blackader oration[1] to the Canadian Medical Association this year, pointed out that the response of a child to punishment depends, in the first place, on his relation with his parents. Where the child is secure in the knowledge that the predominant feeling his parents have for him is love, where the parents are at one with each other, and where the child is able to express his own affection for them, punishment is likely to be most often effective and least often necessary. But the child feels for his parents hostility as well as love, and rightly opines that they feel much the same for him. If at some moment he fears that their hostility outweighs their love, he may go on provoking them to punish him, in order to prove to himself that they are not as dangerous as he fears, and—more important still—to make certain there will be a satisfactory reconciliation afterwards. He is seeking reassurance and love, though his behaviour often gives the opposite impression. But if his fears are well grounded—if he believes with some justice that one or other of his parents is rejecting him—punishment assumes a much more frightening and damaging rôle. It is no longer an incident imposed on a background of affection: it is an expression of enmity; and every time he is punished without satisfactory reconciliation he becomes further estranged from his parents and more convinced that at bottom they hate him. Punishment then loses its effect on his behaviour; and of course this may lead to excessive punishment. From being defiant the child assumes a "don't care" attitude, which is the despair of parents because it makes him inaccessible. Really it is the child's defence against his "intensely painful and damaging" sense of being unloved. Punishment is now an incident against a background of hostility, which the child feels powerless to change. Professor Ellis might have added that the parents, too, may feel powerless to change it. Love is not to be commanded, and some emotionally disturbed children, like some normal children, are harder to love than others. The very utmost their parents may feel able to offer them is kindly treatment; but very few disturbed children are taken in by the counterfeit. In such circumstances they may well be less harassed, and less harassing, with others, anyhow for a time, than they are with their own family: better tepidity from a stranger than dislike from one's own flesh and blood.

The emotionally disturbed child is, of course, likely to get into conflict with more than his parents, and to make himself a nuisance to society at large: and the part which punishment should play in helping him to adjust himself needs consideration. Professor Ellis recognises five types of punishment—vengeance, deterrent punishment, punishment by restitution or atonement, vicarious punishment, and self punishment. While vengeance notoriously relieves the feelings of the bystanders, public opinion has gradually reacted against it. We no longer favour public executions, or the pillory; and we are, he thinks, slowly turning against the use of corporal punishment in schools. Whether or not a given punishment will act as a deterrent, either of the offender, or of others minded to commit his fault, will depend on the attitudes and relationships of the people concerned. If a boy at the gang age feels more loyalty to the gang than to the society he has offended, the deterrent effects of punishment may well be small. Punishment by atonement is a function of self-punishment: a lively conscience demands that the wrongs done to others are made good. Vicarious punishment went out with whipping boys. In the last analysis, punishment by a parent with whom the child is on good terms is reassuring, enabling him in time to take over the ethical standards of the community he lives in, and also the responsibility for seeing that he maintains them. Those who have to deal with maladjusted or delinquent children have therefore to remedy the underlying defect rather than to concentrate on the superficial manifestations of emotional disorder. Their first task is to get the child to realise that adults are not fundamentally hostile, and to provide the background of affection and security which the child lacked in his own home; for, unlike the old lag, he has seldom acquired an irreversible belief in society's hostile intentions. But it is both useless and harmful to persist with methods which have already convinced him that he is among enemies.

This constructive view of punishment, so plainly stated by Professor Ellis, is also implicit in a London County Council pamphlet, *Punishment in Schools*,[2] intended by the council's education inspectorate, who are responsible for the suggestions in it, to stimulate discussion. They note that punishment in schools is declining, that harsh methods by teachers foster harsh standards in pupils, and that corporal punishment should be reserved for special cases which threaten the well-being of the school or class and then used only after other methods have failed. Even then, the pamphlet says, is corporal punishment likely to succeed? The staff, in some schools are so doubtful of its results that they have given it up altogether. Criticism should be good-humoured, sarcasm discarded, detention ordered sparingly. The children should share in the task of maintaining discipline, and be encouraged to take responsibility for their acts and to control their desires. "To be lasting, conformity must come from within, not be imposed from without."

THE STORY OF PERNICIOUS ANÆMIA

A CLOSER acquaintance with the history of medicine adds colour to the plain facts of the textbook, and gives a new significance to the great names of the past. Dr. S. C. Dyke did just this in the first Foundation Lecture of the Association of Clinical Pathologists, which he gave before the meeting of the association in London on Oct. 2. He went back over the past 130 years to trace the Development of the Concept of Pernicious Anæmia.

His story began with James Scarfe Combe, who wrote his examination papers to the sound of the guns of Edinburgh Castle proclaiming the Victory of Waterloo; but the cannonade was not wholly welcome to young Combe, for it meant the frustration of his ambition to become a military surgeon. However he did well enough in civil practice, and in 1824 he wrote the earliest known account of a case of pernicious anæmia. But his work aroused no great interest, and Thomas Addison is generally, though in Dr. Dyke's view mistakenly, considered to have been the first in the field. Addison's supporters point to the description of "a very remarkable form of general anæmia, occurring without any discoverable cause whatever" which prefaces his famous paper of 1849 on the Constitutional and Local Effects of

Disease of the Suprarenal Capsules; but Dr. Dyke thought there was little justification for preserving the name addisonian anæmia.

The next great figures on the scene were Anton Biermer, a Zürich physician who described 15 cases of "progressive pernicious anæmia" in 1872; Julius Cohnheim, the German pathologist, who first noted the fœtal type of bone-marrow; and Samuel Fenwick, physician to the London Hospital, who found the clue to the fundamental lesion in his study of the gastric mucosa. Then, in 1877, Sir Stephen Mackenzie, also of the London, published an account of the natural history of the disease to which little of importance was added for some years. But the pathologists were also at work; the prolific Ehrlich took a hand by introducing revolutionary staining methods and identifying the megaloblast.

A diversion came in 1903 when William Hunter argued convincingly that the disease was a specific infectious fever connected with "an exposure to drain poison," and his views gained wide acceptance. However, the subject soon advanced on to firmer ground; the work of Price-Jones and Boycott on red-cell diameters established that the anæmia was the result of faulty production of red cells and not of excessive destruction; and Peabody, of Boston, fixed the blame on the immature megaloblast.

As Dr. Dyke pointed out, the next and perhaps the most important discovery came in an unexpected way—from work on nutrition. The discovery of the effect of liver in pernicious anæmia earned for Minot, Murphy, and Whipple the Nobel prize in medicine and physiology for 1934. The disease was now being rapidly conquered, and Cohn, of Harvard, made things even better when he prepared liver extracts that were active parenterally. To round off his story, Dr. Dyke outlined the remarkable progress that followed Castle's discovery of the significant defect in gastric digestion—progress with which his audience were more closely familiar. The large pharmaceutical firms had, he said, fostered much of the research on pernicious anæmia in the past ten years or so—research that had culminated in the simultaneous and independent isolation of vitamin B_{12} by Lester Smith in the Glaxo laboratories and by Rickes and his colleagues in the United States.

The Foundation Lectureship of the association has been created in honour of Dr. Dyke, who has been a distinguished member of the association since its earliest days twenty-five years ago, and after the lecture Sir Lionel Whitby presented him with the first Dyke medal.[1]

OTITIS EXTERNA

MUCH bacteriological and mycological work has been done on otitis externa since the outbreak of the late war, for the disease was very common among troops serving overseas and became a serious cause of absence from duty. The latest information comes from Singer and his colleagues[2] in Florida and Texas, who have recently examined cultures from 1377 normal external ears and 646 diseased ones. They isolated over 3000 strains of various organisms and determined their sensitivity to each of seven drugs. Their findings confirm the growing opinion that fungi play only a small part in otitis externa, and that this irritating disorder is usually caused by bacterial infection with *Pseudomonas pyocyanea*; this organism was isolated from as many as 65·5% of the infected ears, but it was found in only 1% of the cultures from normal ears. Most of the organisms were sensitive in vitro to terramycin and many to sulphadiazine, and Singer et al. recommend that these drugs should be given first place in treatment, though they leave the actual method of application to clinical trial.

Alonso[3] studied a smaller series of 82 patients in Puerto Rico, and he was able to isolate fungi from only 7 of them. A distinction was drawn between the acute cases, in which staphylococci were predominant, and the chronic cases, all of which grew *Ps. pyocyanea* on culture. These were also the commonest pathogens in another 100 cases of otitis externa reported from Helsinki by Vaheri and Savolainen[4]; they report good results from local application of the drugs that were indicated by sensitivity tests. They regard otitis externa as primarily a disease of the skin in which infection plays an important but not the only part, either as cause or effect.

In short, laboratory investigations in the last decade or so have shown that otitis externa is commonly a bacterial (and not as was formerly believed a fungous) infection, that the organisms responsible in most cases are *Ps. pyocyanea* and staphylococci, and that good results follow treatment with an antibiotic selected by sensitivity tests. Further clinical trials must be made with terramycin, but it seems probable that complete control of the infective element in otitis externa may still leave an active underlying dermatosis.

DIAGNOSIS OF UNDULANT FEVER

UNDULANT fever is a sporadic disease which simulates many others, and consequently a definite diagnosis can be reached only with the help of the laboratory. The one way of making a certain diagnosis is by recovering the organism from the patient. This is possible in almost all cases during the acute febrile stage or during exacerbations. Blood-culture requires suitable media, which are not available at all centres. In their second report[5] on brucellosis a committee of the National Research Council of America recommends "trypticase-soy" broth or Albimi brucella medium in preference to the older liver-infusion media. Cultures must be incubated in 10% carbon dioxide. Subcultures should be made every 4 days for a month if necessary; Castaneda's technique, which makes use of a rectangular blood-culture bottle layered on one side with agar, avoids the danger of contamination. The bottle is tipped every 48 hours, and the blood-broth mixture flows over the agar surface, thus seeding the foreshore. Since brucella localise in the reticulo-endothelial cells, bone-marrow culture may be positive even after repeated negative blood-cultures; and the organism may also be isolated from lymph-nodes. Occasionally brucella is found in the urine, and in some cases of chronic cholecystitis it has been recovered from the bile. The isolation and identification of brucella from any of these sources takes many days, and repeated examinations may be needed.

A more rapid pointer towards diagnosis is the routine Widal test, although cases may be missed if the serum is not put up in a sufficiently wide range of dilutions. According to the American committee optimal results with the agglutination test are obtained only if incubation at 37°C is continued for 48 hours—a much longer time than is sometimes allowed in this country. There is no easy way of interpreting such tests, but in bacteriologically proved cases of the disease the serum almost always agglutinates at 1 : 100 or over. The agglutination test has the advantage that it is not usually affected by antibiotic therapy, which often sterilises the blood and as often leaves the organisms entrenched in the tissue cells. With clinical recovery from an attack of undulant fever, the serum agglutinins are not usually detectable after a year; but they may persist and cause confusion during some other illness. Immunisation against cholera is yet another pitfall, for the H antigen of the vibrio stimulates agglutinins for the brucella group of organisms. Nevertheless agglutination methods are much easier to carry out than the complement-fixation test, which yields similar results, and the opsonocytophagic test, which is no longer recommended. As with all serological procedures it is wise to demonstrate [illegible]; and this is absolutely essential if the patient has had contact with farm animals.
